Abstract

Fair comparison between diffusion-based OOD detectors is challenging, as conclusions can vary with backbone choice, corruption parameterization, and test-time budget. We address this issue through a *Mutualized Backbone-Equated* (MBE) protocol that aligns canonical corruption levels and logical test-time cost across diffusion backbones. Within this setting, we introduce *Canonical Feature Snapshots* (CFS), a family of detectors that probes a frozen diffusion backbone using only a tiny number of native internal activations at canonical low-noise levels. On a controlled CIFAR-scale benchmark, the strongest one-forward CFS variant is CFS(1×2), while an even smaller decoder-only variant remains highly competitive. This shows that much of the relative-OOD signal exposed by frozen diffusion backbones is concentrated in a small number of sparse internal states, rather than requiring full denoising trajectories or high-capacity downstream heads. We further provide a local diagnostic theory explaining these observations through conditional encoder-decoder complementarity, diagonal-score separation, and low-noise corruption stability. The official implementation is available at <https://github.com/RouzAY/cfs-diffusion-ood/>.

1 Introduction

Out-of-distribution (OOD) detection asks whether a model can identify inputs that fall outside the regime where its predictions should be trusted. In diffusion models, once the backbone is frozen, the same image can be probed across a structured family of corruption levels, producing a hierarchy of hidden states before the final denoising output.

Most diffusion-based OOD methods probe this backbone in *output space*: through reconstructions, denoising residuals, trajectories, output-side geometry, or posterior-consistency scores [Mahmood et al., 2021, Graham et al., 2023, Liu et al., 2023, Gao et al., 2023, Heng et al., 2024, Rouzoumka et al., 2026, Barkley et al., 2026, Shoushtari et al., 2026]. This has produced useful detectors, but it leaves open a more basic question: Within a frozen diffusion backbone, where does the most useful information for OOD detection reside?

We argue that this question is obscured by two coupled issues. The first is *protocol confounding*: in diffusion OOD, conclusions can depend strongly on checkpoint family (e.g., DDPM vs. EDM), corruption coordinates, and test-time budget, much as protocol choices already matter in post-hoc OOD benchmarking more broadly [Yang et al., 2022, Zhang et al., 2024]. The second is representation mismatch: output-space summaries rely on compressed readouts and may miss discriminative information still present in internal states, consistent with the growing view of diffusion models as representation learners [Yang and Wang, 2023, Luo et al., 2023, Yu et al., 2025].

We study this question under a controlled evaluation setting. First, we introduce a *Mutualized Backbone-Equated* (MBE) protocol that aligns checkpoint-family policy, canonical corruption levels, and logical test-time cost across diffusion backbones. Second, within this setting, we propose *Canonical Feature Snapshots* (CFS), a family of OOD detectors that probes a frozen diffusion backbone through a tiny number of aligned internal activations.

On a controlled CIFAR-scale benchmark, the strongest one-forward operating point is $\text{CFS}(1 \times 2)$, while a decoder-only variant, $\text{CFS}_{\text{dec}}(1 \times 1)$, remains highly competitive. Under controlled evaluation, useful OOD signal in frozen diffusion backbones is already strongly concentrated in a tiny number of sparse native internal snapshots.

To explain these trends, we develop a measurable local-testing view of sparse diffusion probing. It yields three diagnostic principles: conditional encoder-decoder complementarity, diagonal-score separation, and low-noise corruption stability. The theory is local rather than universal, but it produces directly estimable quantities for selecting hooks, levels, and encoder-decoder pairings, and we show empirically that these diagnostics track downstream OOD behavior across both improved-diffusion and EDM backbones.

Contributions.

- **A controlled protocol and sparse detector.** We formulate diffusion OOD comparison under a *Mutualized Backbone-Equated* (MBE) protocol, and introduce *Canonical Feature Snapshots* (CFS), a detector family that probes frozen diffusion backbones through a tiny number of aligned internal activations.
- **Evidence that the OOD signal is highly concentrated.** Under MBE, $\text{CFS}(1 \times 2)$ is a strong one-forward operating point, while the single late-decoder probe $\text{CFS}_{\text{dec}}(1 \times 1)$ remains highly competitive, showing that a relevant signal is strongly concentrated in sparse native snapshots.
- **A local diagnostic explanation.** We develop a measurable local-testing view that explains conditional encoder-decoder complementarity, diagonal-score separation, and low-noise stability, and show that its diagnostics track empirical behavior.

2 Related Work and Positioning

Post-hoc OOD detection and protocol sensitivity. A large literature studies post-hoc OOD scores for pretrained discriminative models, including Mahalanobis distances, energy scores, activation shaping, virtual-logit matching, and nearest-neighbor geometry [Lee et al., 2018, Liu et al., 2020, Sun et al., 2021, Wang et al., 2022, Sun et al., 2022, Lu et al., 2025]. Benchmarking efforts such as OpenOOD and OpenOOD v1.5 show how strongly protocol choices can affect conclusions [Yang et al., 2022, Zhang et al., 2024]. These concerns are even sharper in diffusion OOD, where checkpoint family, corruption coordinates, and test-time budget introduce additional confounders.

Diffusion OOD in output space. Most diffusion-based OOD methods probe denoisers through output-space quantities or output-derived summaries. MSMA aggregates multiscale score norms [Mahmood et al., 2021]; DDPM-OOD and LMD use denoising, reconstruction, or inpainting behavior [Graham et al., 2023, Liu et al., 2023]; likelihood-based diffusion OOD has also been studied [Goodier and Campbell, 2023]; DiffGuard adds conditional guidance [Gao et al., 2023]; and DIFFPATH summarizes denoising trajectories from a single unconditional diffusion backbone [Heng et al., 2024]. Other methods use output-side geometric or consistency structure: GEPC measures transformation-induced posterior-consistency violations in denoiser outputs [Rouzoumka et al., 2026], while SCOPED and EigenScore study output-side geometry or uncertainty [Barkley et al., 2026, Shoushtari et al., 2026]. Despite their differences, these methods share the same basic viewpoint: the

Table 1: **Positioning relative to diffusion-based OOD detection.** Our distinction is not merely that internal features can help, but that under a shared-source, backbone-equated protocol, a tiny number of sparse native frozen snapshots already captures a strong relative-OOD signal.

Method	Primary probe	Native internal features	Reconstruction / guidance	Shared-source protocol
MSMA [Mahmood et al., 2021]	multiscale output descriptor	✗	✗	✗
DDPM-OOD [Graham et al., 2023]	reconstruction / manifold	✗	✓	✗
LMD [Liu et al., 2023]	inpainting / reconstruction	✗	✓	✗
DiffGuard [Gao et al., 2023]	guided output probing	✗	✓	✗
DIFFPATH [Heng et al., 2024]	denoising trajectory	✗	✗	✗
GEPC [Rouzoumka et al., 2026]	output consistency	✗	✗	✗
SCOPEd [Barkley et al., 2026]	score geometry	✗	✗	✗
EIGENSCORE [Shoushtari et al., 2026]	covariance geometry	✗	✗	✗
DLSR [Yang et al., 2024]	feature reconstruction	✓	✓	✗
CFS (ours)	sparse native snapshots	✓	✗	✓

OOD signal is extracted primarily from denoiser outputs, reconstructions, trajectories, consistency residuals, or output-side geometry.

Diffusion models as representation learners. A parallel literature views diffusion models as representation learners. Pretrained diffusion backbones provide useful internal features for downstream tasks [Yang and Wang, 2023], and semantically meaningful descriptors can be consolidated from multi-layer and multi-timestep states [Luo et al., 2023]. Related work also suggests encoder/decoder asymmetry: Faster Diffusion reports that encoder activations vary less across denoising steps than decoder activations [Li et al., 2024]. While not an OOD result, this supports the idea that different internal states play different functional roles. REPA further argues that strong hidden representations are important for generation quality [Yu et al., 2025]. Recent OOD work also supports representation-space modeling beyond raw-pixel likelihoods [Ding et al., 2025, Järve et al., 2025]. These works motivate our representation-first viewpoint.

Positioning. We study diffusion OOD under a *Mutualized Backbone-Equated* protocol and ask: under a shared-source, backbone-equated, budget-accounted comparison, how much relative-OOD signal is already present in a tiny number of sparse native frozen snapshots? CFS answers this question with a deliberately minimal detector family: no reconstruction module, no guidance machinery, no reverse-path recursion, and no high-capacity downstream head. Table 1 summarizes CFS positioning.

3 Mutualized Backbone-Equated Protocol (MBE)

OOD benchmarking has shown that evaluation details can dominate perceived progress [Yang et al., 2022, Zhang et al., 2024]. In diffusion OOD, this problem is amplified by additional degrees of freedom, including checkpoint family, corruption parameterization, and hidden test-time budget. We therefore evaluate all methods under a shared protocol designed to remove these confounders.

3.1 Canonical corruption and cross-backbone alignment

A first ingredient of MBE is a shared corruption view across backbone families. Diffusion backbones evaluate corrupted versions of an input across a family of noise levels [Ho et al., 2020, Nichol and Dhariwal, 2021, Karras et al., 2022], but their native interfaces differ: some expose discrete timesteps t , while others use continuous noise scales such as σ . To compare OOD detectors across backbones, we therefore work with a common canonical corruption parameterization.

For a clean sample \mathbf{x}_0 , we write corruption as

$$\mathbf{x}_\lambda = a(\lambda)\mathbf{x}_0 + b(\lambda)\boldsymbol{\varepsilon}, \quad \boldsymbol{\varepsilon} \sim \mathcal{N}(0, I), \quad (1)$$

and use the canonical coordinate, with a slight abuse of notation,

$$\lambda := \log \frac{a(\lambda)^2}{b(\lambda)^2}, \quad (2)$$

i.e., $\log\text{SNR}$. Large λ corresponds to cleaner observations and small λ to noisier ones.

For improved-diffusion checkpoints, $a_t = \sqrt{\bar{\alpha}_t}$, $b_t = \sqrt{1 - \bar{\alpha}_t}$, and $\lambda_t = \log \frac{\bar{\alpha}_t}{1 - \bar{\alpha}_t}$, so a desired canonical level is matched to the nearest native timestep in $\log\text{SNR}$ space. EDM-style backbones instead expose a continuous noise input; our adapter maps each canonical λ to the appropriate

backbone-specific model input and returns coefficients satisfying Eq. (1). Canonicalization matters because many diffusion OOD methods are intrinsically multilevel: without a shared corruption coordinate, methods may be compared at levels that are not actually matched in corruption strength.

3.2 Controlled comparison under MBE

Under MBE, a method is evaluated under the same source-family policy, preprocessing, canonical corruption levels, ID/OOD splits, and logical test-time cost as its competitors. The purpose of MBE is scientific comparison, not per-backbone peak tuning. A diffusion OOD method can otherwise appear stronger for reasons unrelated to its scoring rule: a better-matched checkpoint, a different input normalization, a different corruption coordinate, or a larger hidden test-time budget.

Concretely, MBE routes all methods through the same canonical corruption semantics and shared adapter interface, and evaluates them under the same split policy and logical budget accounting. It does not force identical native implementations. Detailed canonicalization, adapter outputs, and baseline implementation taxonomy are deferred to Appendix C and Appendix D.

For discrete backbones, mapping a continuous logSNR grid to native timesteps can produce duplicates. We therefore distinguish the candidate grid resolution K_{grid} from the number of effective canonical levels K_c actually used by a method; Appendix C.3–C.4 gives the precise construction.

We report the logical test-time cost as

$$\text{Cost}_m = \#F_m + \#J_m,$$

where $\#F_m$ is the number of backbone forward evaluations per image and $\#J_m$ the number of Jacobian-type evaluations when applicable. In the main comparisons of this paper, the dominant variation is in $\#F$, and all compared methods have $\#J = 0$.

4 Method: Canonical Feature Snapshots (CFS)

4.1 Canonical Feature Snapshots

We ask whether a tiny number of native frozen internal activations already captures useful OOD signal once protocol confounders are removed. Let P_* denote the source distribution used to train a frozen diffusion checkpoint, and let P and Q denote the evaluation ID and OOD datasets. We do not treat the checkpoint as an OOD oracle for P_* ; instead, we use it as a frozen representation map and define OOD relative to the evaluation reference bank P .

A CFS instance is specified by a small set of canonical levels Λ , a small set of native internal hooks \mathcal{H} , and an ID-only scoring head on the resulting pooled slot descriptors. For each $\lambda \in \Lambda$, we form

$$\mathbf{x}_\lambda = a(\lambda)\mathbf{x}_0 + b(\lambda)\boldsymbol{\varepsilon}, \quad \boldsymbol{\varepsilon} \sim \mathcal{N}(\mathbf{0}, \mathbf{I}),$$

run one forward pass through the frozen diffusion backbone, and pool each selected activation $\mathbf{u}_{\lambda,h}(\mathbf{x}_\lambda)$ into a descriptor

$$\mathbf{z}_{\lambda,h}(\mathbf{x}_0) := \text{Pool}(\mathbf{u}_{\lambda,h}(\mathbf{x}_\lambda)).$$

The sparse representation is

$$\Phi(\mathbf{x}_0) = [\mathbf{z}_{\lambda,h}(\mathbf{x}_0)]_{(\lambda,h) \in \mathcal{S}}, \quad \mathcal{S} \subseteq \Lambda \times \mathcal{H}.$$

OOD detection then reduces to fitting ID-only slot statistics on $\Phi(P)$ and scoring deviation from that reference geometry.

The paper focuses on two operating points: CFS(1×2), which uses one deep encoder and one late decoder hook at a single low-noise level, and CFS_{dec}(1×1), a decoder-only variant. Because all retained hooks at a fixed level are captured within the same backbone forward pass, logical cost depends only on the number of selected levels:

$$\#F_{\text{CFS}} = |\Lambda|, \quad \#J_{\text{CFS}} = 0.$$

Figure 1 summarizes this pipeline.

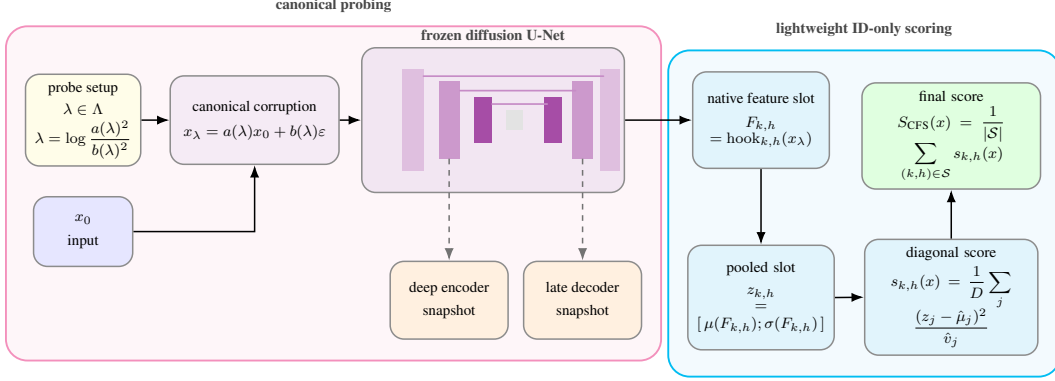

Figure 1: **Overview of CFS.** The input is corrupted at a canonical level, processed by a frozen diffusion U-Net, probed through a small number of native internal snapshots, and scored with a lightweight ID-only head.

4.2 A local diagnostic view

Our theory is local and diagnostic rather than universal: it asks which frozen internal statistics should be most useful for testing membership in the evaluation ID reference distribution, and it focuses on quantities directly measurable on held-out data.

Fix a canonical level λ . Let $\mathbf{z}_{d,\lambda}(\mathbf{x}_0)$ and $\mathbf{z}_{e,\lambda}(\mathbf{x}_0)$ denote a selected late decoder snapshot and a selected deep encoder snapshot, and define

$$\mathbf{z}_\lambda(\mathbf{x}_0) = [\mathbf{z}_{d,\lambda}(\mathbf{x}_0)^\top, \mathbf{z}_{e,\lambda}(\mathbf{x}_0)^\top]^\top.$$

We use the local testing approximation

$$\mathbf{z}_\lambda(\mathbf{x}_0) \mid H_0 \sim \mathcal{N}(\boldsymbol{\mu}_\lambda, \boldsymbol{\Sigma}_\lambda), \quad \mathbf{z}_\lambda(\mathbf{x}_0) \mid H_1 \sim \mathcal{N}(\boldsymbol{\mu}_\lambda + \boldsymbol{\Delta}_\lambda, \boldsymbol{\Sigma}_\lambda), \quad (3)$$

where $H_0 : \mathbf{x}_0 \sim P$ and $H_1 : \mathbf{x}_0 \sim Q$. This is a local model on pooled internal representations, not a global image model.

Theorem 1 (Conditional encoder-decoder complementarity). *Under Eq. (3), the paired separation decomposes as*

$$\text{Sep}_{\text{pair}}(\lambda) = \text{Sep}_{\text{dec}}(\lambda) + \text{Res}_{e|d}(\lambda), \quad \text{Res}_{e|d}(\lambda) \geq 0.$$

The residual vanishes iff the encoder shift is fully explained by the decoder shift. Hence

$$\text{Sep}_{\text{pair}}(\lambda) \geq \text{Sep}_{\text{dec}}(\lambda).$$

The full expression is given in Appendix B.3.

Thus, the local model supports treating the late decoder as the primary sparse probe, while viewing the encoder as a complementary source of residual information.

Proposition 1 (Low-noise corruption stability). *Let*

$$\mathbf{x}_\lambda = a(\lambda)\mathbf{x}_0 + b(\lambda)\boldsymbol{\varepsilon}, \quad \boldsymbol{\varepsilon} \sim \mathcal{N}(\mathbf{0}, \mathbf{I}), \quad \mathbf{z}_{\lambda,h}(\mathbf{x}_0) = \phi_{\lambda,h}(\mathbf{x}_\lambda).$$

Assume that $\phi_{\lambda,h}$ admits a first-order mean-square expansion around $a(\lambda)\mathbf{x}_0$, with Jacobian

$$\mathbf{J}_{\lambda,h}(\mathbf{x}_0) := \nabla_{\mathbf{x}} \phi_{\lambda,h}(\mathbf{x}) \Big|_{\mathbf{x}=a(\lambda)\mathbf{x}_0}.$$

Then, conditionally on \mathbf{x}_0 ,

$$\mathbb{E}[\|\mathbf{z}_{\lambda,h}(\mathbf{x}_0) - \phi_{\lambda,h}(a(\lambda)\mathbf{x}_0)\|_2^2 \mid \mathbf{x}_0] = b(\lambda)^2 \text{tr}(\mathbf{J}_{\lambda,h}(\mathbf{x}_0)\mathbf{J}_{\lambda,h}(\mathbf{x}_0)^\top) + o(b(\lambda)^2). \quad (4)$$

Thus, the within-image corruption variance of the hooked representation is first-order proportional to $b(\lambda)^2$.

Finally, Appendix B.2 shows that the oracle diagonal score has mean 1 under H_0 and $1 + \kappa_\lambda/d_\lambda$ under H_1 , where

$$\mathbf{D}_\lambda = \text{diag}(\boldsymbol{\Sigma}_\lambda), \quad \kappa_\lambda = \boldsymbol{\Delta}_\lambda^\top \mathbf{D}_\lambda^{-1} \boldsymbol{\Delta}_\lambda, \quad d_\lambda = \dim(\mathbf{z}_\lambda).$$

These results motivate two diagnostics:

$$\hat{\kappa}_\lambda(\mathcal{S}), \quad \hat{R}_h(\lambda),$$

corresponding to the estimated diagonal separation and content-to-instability ratio. Their operational estimators are introduced in the next subsection, while their formal analysis and supplementary interpretation are deferred to Appendix B.

4.3 Hook selection and lightweight scoring

We hook *block outputs* rather than arbitrary leaf submodules. This improves portability across architectures and avoids unstable low-level activations. The local theory suggests two priorities: late decoder states are the primary candidates, and a deep encoder hook, when used, should be interpreted as complementary residual information.

Within each structural region, we refine the final choice with a small ID-only proxy. For candidate module m , let $\mathbf{z}_{i,r}^{(m)}$ be its pooled feature for image i under corruption draw r , averaged over the selected canonical levels, and let

$$\bar{\mathbf{z}}_i^{(m)} = \frac{1}{R} \sum_{r=1}^R \mathbf{z}_{i,r}^{(m)}.$$

We estimate

$$\widehat{\mathbf{C}}_{\text{img}}^{(m)} = \widehat{\text{Cov}}_i(\bar{\mathbf{z}}_i^{(m)}), \quad \widehat{\mathbf{C}}_{\text{corr}}^{(m)} = N^{-1} \sum_{i=1}^N \widehat{\text{Cov}}_r(\mathbf{z}_{i,r}^{(m)}),$$

and score the candidate by

$$\text{Proxy}(m) = \frac{\text{tr} \widehat{\mathbf{C}}_{\text{img}}^{(m)}}{\text{tr} \widehat{\mathbf{C}}_{\text{corr}}^{(m)}}. \quad (5)$$

This favors modules that vary across ID images while remaining stable under stochastic corruption at fixed content.

For a selected slot (k, ℓ) , let

$$\mathbf{F}_{k,\ell}(\mathbf{x}_0) \in \mathbb{R}^{C_{k,\ell} \times H_{k,\ell} \times W_{k,\ell}}$$

denote the hooked feature map. We use the pooled descriptor

$$\mathbf{z}_{k,\ell}(\mathbf{x}_0) = [\text{Mean}_{\text{sp}}(\mathbf{F}_{k,\ell}(\mathbf{x}_0))^\top, \text{Std}_{\text{sp}}(\mathbf{F}_{k,\ell}(\mathbf{x}_0))^\top]^\top \in \mathbb{R}^{D_{k,\ell}}, \quad (6)$$

where Mean_{sp} and Std_{sp} are channel-wise spatial mean and standard deviation. Using only ID-train data, we fit diagonal statistics $(\hat{\boldsymbol{\mu}}_{k,\ell}, \hat{\mathbf{v}}_{k,\ell})$. The slot score is

$$s_{k,\ell}(\mathbf{x}_0) = \frac{1}{D_{k,\ell}} \sum_{j=1}^{D_{k,\ell}} \frac{\left(\mathbf{z}_{k,\ell}^{(j)}(\mathbf{x}_0) - \hat{\boldsymbol{\mu}}_{k,\ell}^{(j)} \right)^2}{\hat{\mathbf{v}}_{k,\ell}^{(j)}}, \quad (7)$$

and the final score is

$$S_{\text{CFS}}(\mathbf{x}_0) = \frac{1}{|\mathcal{S}|} \sum_{(k,\ell) \in \mathcal{S}} s_{k,\ell}(\mathbf{x}_0). \quad (8)$$

We intentionally use a lightweight diagonal score, also referred to as an ID-only score or ID-only proxy: CFS is meant to test the quality of sparse frozen representations, not to rely on a high-capacity downstream classifier. While stronger downstream heads may improve absolute performance, they would partially confound the representation-quality interpretation targeted by MBE. Alternative heads are therefore reported only as analysis in Appendix E.6. For the local diagnostics, we estimate

$$\hat{\kappa}_\lambda(\mathcal{S}) = \hat{\boldsymbol{\Delta}}_{\lambda,\mathcal{S}}^\top \hat{\mathbf{D}}_{\lambda,\mathcal{S}}^{-1} \hat{\boldsymbol{\Delta}}_{\lambda,\mathcal{S}}, \quad \hat{R}_h(\lambda) = \frac{\text{tr} \widehat{\mathbf{C}}_{\text{img}}^{(h,\lambda)}}{\text{tr} \widehat{\mathbf{C}}_{\text{corr}}^{(h,\lambda)}}.$$

These diagnostics are not used to fit the detector; they only test whether sparse hooks and canonical levels behave as predicted by the local theory.

5 Experiments

5.1 Setup

Our main benchmark is CIFAR-scale, where protocol control is the cleanest. We use

$$\begin{aligned}\mathcal{I}_{\text{small}} &= \{\text{CIFAR-10, SVHN, CelebA32}\}, \\ \mathcal{O}_{\text{small}} &= \{\text{CIFAR-10, SVHN, CelebA32, CIFAR-100, DTD}\}.\end{aligned}$$

For each $i \in \mathcal{I}_{\text{small}}$, all datasets in $\mathcal{O}_{\text{small}} \setminus \{i\}$ are treated as OOD, yielding 12 ID→OOD pairs per backbone.

We evaluate two diffusion backbone families through the same adapter and canonical corruption interface: improved-diffusion backbones with discrete timesteps and native ε -prediction, and EDM-family backbones with continuous noise conditioning and one-shot \hat{x}_0 estimation. In the main benchmark, all methods use a shared CIFAR-10 checkpoint family; we then repeat the same benchmark with a shared CelebA32 checkpoint family for source-family robustness. Larger-scale ImageNet transfer results are deferred to the Appendix I.

5.2 Baselines and metrics

All baselines are evaluated under the shared MBE pipeline. Our main comparators are MSMA [Mahmood et al., 2021], DIFFPATH [Heng et al., 2024], DDPM-OOD [Graham et al., 2023], and GEPC [Rouzoumka et al., 2026]. Detailed baseline taxonomy and implementation choices are deferred to Appendix C and Appendix D.

Unless stated otherwise, the main paper operating point is CFS(1×2), a one-level two-hook variant using paired encoder and decoder snapshots at the same low-noise canonical level. We also report CFS_{dec}(1×1), a decoder-only companion. Richer variants such as CFS(2×2) and CFS(2×4) are studied in the Appendix E.1.

All methods output OOD-high scores. Our primary metric is AUROC; full FPR95 breakdowns are reported in the appendix. Across pairs, we summarize performance by

$$\text{AvgAUROC}_{m,b} = \frac{1}{|\mathcal{P}|} \sum_{p \in \mathcal{P}} \text{AUROC}_{m,b}(p), \quad (9)$$

$$\text{AvgWorstAUROC}_{m,b} = \frac{1}{|\mathcal{I}|} \sum_{i \in \mathcal{I}} \min_{o \in \mathcal{O}(i)} \text{AUROC}_{m,b}(i \rightarrow o), \quad (10)$$

and report logical test-time $\text{Cost}_m = \#F_m + \#J_m$ (with $\#J_m = 0$ for all main-paper comparisons).

Appendix E.9 provides an architecture-transfer sanity check on U-ViT, where CFS is applied to early/middle/late transformer block snapshots rather than U-Net encoder/decoder maps.

6 Results

Claim scope. Our claim is strictly about controlled comparison under MBE: when source-family policy, canonical corruption semantics, and logical test-time cost are matched, sparse native snapshot probing is stronger than the output-space alternatives we evaluate at comparable or lower logical cost.

6.1 Main CIFAR-scale comparison under MBE

Table 2 reports the main controlled CIFAR-scale comparison under MBE.

At a one-forward budget, CFS(1×2) is the strongest operating point on both backbone families. Relative to the strongest harmonized output-space baselines, it improves AvgWorstAUROC from 0.689 to 0.814 on EDM and from 0.688 to 0.799 on improved-diffusion, while reducing logical cost from 8–10 forwards per image to 1. At the same time, CFS_{dec}(1×1) remains extremely close, showing that the representation-space gain is not only strong but also highly compressible. Budget-matched ablations are reported in Appendix E.1.

Table 2: **Main comparison under MBE on the CIFAR-scale benchmark.** IDs: CIFAR-10, SVHN, CelebA32. OODs: the remaining datasets among {CIFAR-10, SVHN, CelebA32, CIFAR-100, DTD}, yielding 12 pairs per backbone. All methods use the same source-family policy, preprocessing, canonical corruption construction, and split policy. Best and second-best results are highlighted in bold and underline, respectively. Complementary results are available in Appendix F.

Method	Backbone	AvgAUROC \uparrow	AvgWorstAUROC \uparrow	$\#F/\text{img}$ \downarrow	Notes
MSMA	improved	0.792	0.688	10	multiscale output descriptor
MSMA	EDM	0.796	0.689	10	multiscale output descriptor
DIFFPATH	improved	0.778	0.641	10	recursive path statistic
DIFFPATH	EDM	0.792	0.635	10	recursive path statistic
DDPM-OOD	improved	0.550	0.316	364	reconstruction / manifold
DDPM-OOD	EDM	0.559	0.320	364	reconstruction / manifold
GEPC	improved	0.616	0.546	8	output-space consistency
GEPC	EDM	0.774	0.600	8	output-space consistency
CFS_{dec}(1×1)	improved	<u>0.886</u>	<u>0.793</u>	1	single snapshot at low noise
CFS_{dec}(1×1)	EDM	0.919	<u>0.809</u>	1	single snapshot at low noise
CFS(1×2)	improved	0.887	0.799	1	paired snapshots at low noise
CFS(1×2)	EDM	<u>0.916</u>	0.814	1	paired snapshots at low noise

Table 3: **Empirical validation of the measurable theory diagnostics.** Spearman correlations are computed across candidate sparse probes and ID→OOD pairs. The diagnostics are not used to fit the detector; they only test whether the measured behavior of sparse hooks and canonical levels agrees with the local theory.

Diagnostic	Backbone	Spearman ρ
$\hat{\kappa}_\lambda(\mathcal{S})/d$ vs AUROC	improved	0.923
$\hat{\kappa}_\lambda(\mathcal{S})/d$ vs AUROC	EDM	0.938
$\hat{R}_h(\lambda)$ vs Avg AUROC	improved	0.862
$\hat{R}_h(\lambda)$ vs Avg AUROC	EDM	0.760

DLSR is the closest prior in spirit, but it lies outside our MBE protocol because it introduces an additional learned feature-reconstruction module. Since DLSR is only available on its native published evaluation pairs, we report a comparison on that DLSR-native subset in Table 20 of Appendix H.1.

6.2 Theory diagnostics: measurable quantities predict sparse-probe quality

We next test whether the local-testing theory yields measurable quantities that predict sparse-probe quality. It does (see Table 3).

First, the diagonal noncentrality diagnostic $\hat{\kappa}_\lambda(\mathcal{S})/d$ is strongly aligned with downstream OOD performance across both backbone families: candidate sparse probes with larger estimated diagonal separation consistently yield larger AUROC. This supports the interpretation of the diagonal score as a local detector. Representative diagnostic scatter plots for $\hat{\kappa}_\lambda(\mathcal{S})/d$ versus AUROC are deferred to Appendix B.7.

Second, the content-to-instability ratio $\hat{R}_h(\lambda)$ is also strongly predictive of hook quality. Moreover, the within-image corruption variance decreases sharply as $b(\lambda)^2$ decreases, in agreement with Proposition 1, supporting the low-noise advantage. Appendix B.7 reports the complementary $\hat{R}_h(\lambda)$ and low-noise stability plots.

6.3 Focused ablations

The appendix addresses three narrower questions: whether the gain is explained by hidden test-time budget in Appendix E.1, whether the gain is driven by head complexity rather than representation quality (see Appendix E.4), and whether the ranking is stable across stochastic seeds through Appendix E.8. Across all cases, the central conclusion is unchanged: the gain comes primarily from *where* the frozen backbone is probed.

Table 4: **External positioning outside MBE (single-checkpoint setting only)**. Prior-method results are taken from the respective papers or officially reported artifacts. Full results are in Appendix H.

Method	Avg. AUROC \uparrow	Cost \downarrow
SCOPED-CelebA	0.892	2F+2J
GEPC-CelebA	0.910	8F
DiffPath-6D-CelebA	0.931	10F
DiffPath-6D-ImageNet	0.850	10F
CFS(1\times2)-CelebA (ours)	<u>0.935</u>	1F
CFS(1\times2)-ImageNet (ours)	0.962	1F

Table 5: **Source-family robustness on the CIFAR-scale benchmark**. Same protocol as Table 2, but with a shared CelebA32 checkpoint family. More experiments are exposed in Appendix G.

Method	Improved		EDM		#F/img \downarrow
	AvgAUROC \uparrow	AvgWorstAUROC \uparrow	AvgAUROC \uparrow	AvgWorstAUROC \uparrow	
MSMA	0.881	0.808	0.790	0.673	10
DIFFPATH	0.829	0.743	0.776	0.650	10
DDPM-ODD	0.581	0.362	0.575	0.325	364
GEPC	0.749	0.650	0.745	0.648	<u>8</u>
CFS_{dec}(1\times1)	<u>0.907</u>	<u>0.823</u>	<u>0.914</u>	<u>0.827</u>	1
CFS(1\times2)	0.908	0.827	0.928	0.846	1

Hook-selection robustness. The ID-only hook-selection proxy does not need to recover the exact oracle pair to be effective. On improved-diffusion, the selected pair reaches 0.886 AvgAUROC versus 0.895 for the best admissible pair, while on EDM, the pairwise landscape exhibits a broad plateau of strong pairs. This indicates that CFS(1 \times 2) is not driven by brittle hook cherry-picking; see Appendix E.2.

External positioning outside MBE. Table 4 provides a non-protocol-matched positioning against previously reported diffusion-ODD results. These comparisons are included for external positioning.

6.4 Source-family robustness

In Table 5, we repeat the same CIFAR-scale benchmark with a shared CelebA32 source family to test whether the ranking persists after changing the frozen source representation.

The ordering remains essentially unchanged under both source families: CFS(1 \times 2) remains best on both backbone families, and CFS_{dec}(1 \times 1) remains a near-tied one-forward companion. This argues against a checkpoint-family artifact and supports the probing-space interpretation.

7 Discussion and Limitations

Once protocol confounders are removed, the main bottleneck is not simply *more output-space engineering*, but *where* the frozen diffusion backbone is probed. Our results suggest that a small number of native internal snapshots can retain relative-ODD geometry that output-space summaries partly attenuate. In this sense, CFS should be read not only as a score family, but as evidence that, under controlled MBE comparison, a representation-first probing strategy can be more informative than broader output-space summaries. Across controlled comparisons, CFS(1 \times 2) is the strongest one-forward operating point, while the sparse CFS_{dec}(1 \times 1) remains remarkably competitive, showing that a large fraction of the useful signal is already concentrated in a single late decoder snapshot.

Limitations. CFS requires internal access to the diffusion backbone and is therefore less black-box than output-space scores. Its portability is structural rather than representational: canonical levels can be aligned across backbones, but internal features remain architecture and source-dependent. Hard multimodal ID regimes such as CIFAR-10 remain challenging. Finally, our theory is intentionally local rather than universal.

8 Conclusion

We introduced MBE, a protocol for fair cross-backbone diffusion OOD evaluation, and CFS, a family of minimal representation-space detectors based on sparse native internal snapshots. Under MBE, the strongest one-forward operating point in our main controlled comparisons is CFS(1×2), while the even sparser CFS_{dec}(1×1) remains remarkably competitive. More broadly, once protocol confounders are removed, strong relative diffusion OOD detection can already be obtained far upstream of elaborate output-space probes: a tiny number of sparse, canonically aligned internal snapshots captures a large fraction of the useful relative-OOD geometry.

A Appendix Roadmap

This appendix supports the paper’s central claim: under a backbone-equated protocol, a frozen diffusion checkpoint can be used as a relative-OOD representation map, and a tiny number of sparse low-noise internal snapshots already captures strong useful signal.

It is organized as follows:

- Section **B**: proofs and supplementary validations for the main-paper theory, including conditional encoder-decoder complementarity, low-noise corruption stability, diagonal-score separation, canonical-level matching, and the interpretation of the hook-selection proxy.
- Sections **C–D**: shared protocol, canonicalization, logical cost accounting, and harmonized baseline implementations.
- Section **E**: focused ablations testing budget, hook robustness, canonical-level robustness, pooling, head choice, bank size, and seed stability.
- Sections **F** and **G**: full CIFAR-scale pairwise results under the primary and alternative source-family policies.
- Section **H**: external positioning against prior reported diffusion-based CIFAR-scale results outside the controlled MBE protocol.
- Section **I**: checkpoint-controlled large-scale results on ImageNet200 and ImageNet1K using a single official ImageNet-64 improved-diffusion backbone.
- Section **J**: implementation and configuration details, including the main CFS hyperparameters, ID-only head configurations, determinism settings, profiling protocol, and representative compute-resource reporting.
- Section **K**: broader impact and responsible-use discussion.

Unless noted otherwise, appendix ablations are centered on CFS(1×2), the primary main-paper operating point. We retain CFS_{dec}(1×1) only in targeted controls where the compression result is directly relevant.

B Theory Appendix

This appendix supplies the formal statements, proofs, and supplementary validations supporting the main paper theory. The main text relies directly on two load-bearing claims: conditional encoder-decoder complementarity and low-noise corruption stability. We additionally formalize here the diagonal-score separation result deferred from the main text, a canonical-level stability bound under discretization, and a formal interpretation of the hook-selection proxy.

B.1 Notation

Fix a frozen diffusion backbone and evaluation domains P and Q , corresponding to the relative ID and OOD distributions. For a canonical corruption level λ ,

$$\mathbf{x}_\lambda = a(\lambda) \mathbf{x}_0 + b(\lambda) \boldsymbol{\varepsilon}, \quad \boldsymbol{\varepsilon} \sim \mathcal{N}(\mathbf{0}, \mathbf{I}).$$

For a selected late decoder hook and a selected deep encoder hook,

$$\mathbf{z}_\lambda(\mathbf{x}_0) = \begin{bmatrix} \mathbf{z}_{d,\lambda}(\mathbf{x}_0) \\ \mathbf{z}_{e,\lambda}(\mathbf{x}_0) \end{bmatrix},$$

and the local model is

$$\mathbf{z}_\lambda(\mathbf{x}_0) \mid H_0 \sim \mathcal{N}(\boldsymbol{\mu}_\lambda, \boldsymbol{\Sigma}_\lambda), \quad \mathbf{z}_\lambda(\mathbf{x}_0) \mid H_1 \sim \mathcal{N}(\boldsymbol{\mu}_\lambda + \boldsymbol{\Delta}_\lambda, \boldsymbol{\Sigma}_\lambda),$$

with $H_0 : \mathbf{x}_0 \sim P$ and $H_1 : \mathbf{x}_0 \sim Q$.

B.2 Deferred statement from the main text

The following result is used in the interpretation of the diagonal CFS score, but is deferred here to keep the main text focused.

Let

$$\mathbf{D}_\lambda = \text{diag}(\boldsymbol{\Sigma}_\lambda), \quad d_\lambda = \text{dim}(\mathbf{z}_\lambda),$$

and consider the oracle diagonal score

$$s_\lambda^\circ(\mathbf{z}) := \frac{1}{d_\lambda} (\mathbf{z} - \boldsymbol{\mu}_\lambda)^\top \mathbf{D}_\lambda^{-1} (\mathbf{z} - \boldsymbol{\mu}_\lambda), \quad \kappa_\lambda := \boldsymbol{\Delta}_\lambda^\top \mathbf{D}_\lambda^{-1} \boldsymbol{\Delta}_\lambda.$$

Theorem 2 (Diagonal-score separation under the local model). *Under Eq. (3),*

$$\mathbb{E}_{H_0}[s_\lambda^\circ] = 1, \quad \mathbb{E}_{H_1}[s_\lambda^\circ] = 1 + \frac{\kappa_\lambda}{d_\lambda}.$$

Moreover, the variance of s_λ° is controlled by the correlation structure of Σ_λ , yielding the detection-power bound proved below.

B.3 Proof of Theorem 1

Proof. Write

$$\Delta_\lambda = \begin{bmatrix} \Delta_{d,\lambda} \\ \Delta_{e,\lambda} \end{bmatrix}, \quad \Sigma_\lambda = \begin{bmatrix} \Sigma_{dd,\lambda} & \Sigma_{de,\lambda} \\ \Sigma_{ed,\lambda} & \Sigma_{ee,\lambda} \end{bmatrix}.$$

The paired Mahalanobis separation is

$$\text{Sep}_{\text{pair}}(\lambda) = \Delta_\lambda^\top \Sigma_\lambda^{-1} \Delta_\lambda,$$

while the decoder-only separation is

$$\text{Sep}_{\text{dec}}(\lambda) = \Delta_{d,\lambda}^\top \Sigma_{dd,\lambda}^{-1} \Delta_{d,\lambda}.$$

Let

$$\Sigma_{e|d,\lambda} = \Sigma_{ee,\lambda} - \Sigma_{ed,\lambda} \Sigma_{dd,\lambda}^{-1} \Sigma_{de,\lambda},$$

be the Schur complement of the decoder block. By the block inverse formula,

$$\Sigma_\lambda^{-1} = \begin{bmatrix} \Sigma_{dd,\lambda}^{-1} + \Sigma_{dd,\lambda}^{-1} \Sigma_{de,\lambda} \Sigma_{e|d,\lambda}^{-1} \Sigma_{ed,\lambda} \Sigma_{dd,\lambda}^{-1} & -\Sigma_{dd,\lambda}^{-1} \Sigma_{de,\lambda} \Sigma_{e|d,\lambda}^{-1} \\ -\Sigma_{e|d,\lambda}^{-1} \Sigma_{ed,\lambda} \Sigma_{dd,\lambda}^{-1} & \Sigma_{e|d,\lambda}^{-1} \end{bmatrix}.$$

Substituting this expression into $\Delta_\lambda^\top \Sigma_\lambda^{-1} \Delta_\lambda$ and collecting terms gives

$$\text{Sep}_{\text{pair}}(\lambda) = \text{Sep}_{\text{dec}}(\lambda) + \text{Res}_{e|d}(\lambda),$$

where

$$\text{Res}_{e|d}(\lambda) = \left(\Delta_{e,\lambda} - \Sigma_{ed,\lambda} \Sigma_{dd,\lambda}^{-1} \Delta_{d,\lambda} \right)^\top \Sigma_{e|d,\lambda}^{-1} \left(\Delta_{e,\lambda} - \Sigma_{ed,\lambda} \Sigma_{dd,\lambda}^{-1} \Delta_{d,\lambda} \right).$$

Since $\Sigma_{e|d,\lambda} \succ 0$, the residual term is nonnegative. Therefore

$$\text{Sep}_{\text{pair}}(\lambda) \geq \text{Sep}_{\text{dec}}(\lambda).$$

Equality holds if and only if the conditional residual vanishes, namely

$$\Delta_{e,\lambda} = \Sigma_{ed,\lambda} \Sigma_{dd,\lambda}^{-1} \Delta_{d,\lambda}.$$

This proves the decomposition and the claimed nonnegativity. \square

B.4 Proof of Proposition 1

Proof. Fix \mathbf{x}_0 and write

$$\mathbf{x}_\lambda = a(\lambda) \mathbf{x}_0 + b(\lambda) \boldsymbol{\varepsilon}.$$

By the assumed first-order mean-square expansion of $\phi_{\lambda,h}$ around $a(\lambda)\mathbf{x}_0$, we have

$$\phi_{\lambda,h}(\mathbf{x}_\lambda) = \phi_{\lambda,h}(a(\lambda)\mathbf{x}_0) + b(\lambda) \mathbf{J}_{\lambda,h}(\mathbf{x}_0) \boldsymbol{\varepsilon} + \mathbf{r}_{\lambda,h}(\mathbf{x}_0, \boldsymbol{\varepsilon}),$$

with

$$\mathbb{E} \left[\|\mathbf{r}_{\lambda,h}(\mathbf{x}_0, \boldsymbol{\varepsilon})\|_2^2 \mid \mathbf{x}_0 \right] = o(b(\lambda)^2).$$

Therefore,

$$\mathbf{z}_{\lambda,h}(\mathbf{x}_0) - \phi_{\lambda,h}(a(\lambda)\mathbf{x}_0) = b(\lambda) \mathbf{J}_{\lambda,h}(\mathbf{x}_0) \boldsymbol{\varepsilon} + \mathbf{r}_{\lambda,h}(\mathbf{x}_0, \boldsymbol{\varepsilon}).$$

Taking squared norms and conditional expectations gives

$$\mathbb{E} \left[\|\mathbf{z}_{\lambda,h}(\mathbf{x}_0) - \phi_{\lambda,h}(a(\lambda)\mathbf{x}_0)\|_2^2 \mid \mathbf{x}_0 \right] = b(\lambda)^2 \mathbb{E} \left[\|\mathbf{J}_{\lambda,h}(\mathbf{x}_0) \boldsymbol{\varepsilon}\|_2^2 \right] + o(b(\lambda)^2).$$

Since $\boldsymbol{\varepsilon} \sim \mathcal{N}(\mathbf{0}, \mathbf{I})$,

$$\mathbb{E} \left[\|\mathbf{J}_{\lambda,h}(\mathbf{x}_0) \boldsymbol{\varepsilon}\|_2^2 \right] = \text{tr}(\mathbf{J}_{\lambda,h}(\mathbf{x}_0) \mathbf{J}_{\lambda,h}(\mathbf{x}_0)^\top).$$

Hence

$$\mathbb{E} \left[\|\mathbf{z}_{\lambda,h}(\mathbf{x}_0) - \phi_{\lambda,h}(a(\lambda)\mathbf{x}_0)\|_2^2 \mid \mathbf{x}_0 \right] = b(\lambda)^2 \text{tr}(\mathbf{J}_{\lambda,h}(\mathbf{x}_0) \mathbf{J}_{\lambda,h}(\mathbf{x}_0)^\top) + o(b(\lambda)^2),$$

which proves the result. \square

B.5 Proof of Theorem 2

Proof. Let

$$\mathbf{D}_\lambda = \text{diag}(\boldsymbol{\Sigma}_\lambda), \quad \mathbf{R}_\lambda = \mathbf{D}_\lambda^{-1/2} \boldsymbol{\Sigma}_\lambda \mathbf{D}_\lambda^{-1/2}, \quad \boldsymbol{\delta}_\lambda = \mathbf{D}_\lambda^{-1/2} \boldsymbol{\Delta}_\lambda.$$

Define the whitened-but-correlated variable

$$\mathbf{y} = \mathbf{D}_\lambda^{-1/2} (\mathbf{z} - \boldsymbol{\mu}_\lambda).$$

Under H_0 , we have

$$\mathbf{y} \sim \mathcal{N}(\mathbf{0}, \mathbf{R}_\lambda),$$

and under H_1 ,

$$\mathbf{y} \sim \mathcal{N}(\boldsymbol{\delta}_\lambda, \mathbf{R}_\lambda).$$

The oracle diagonal score can be written as

$$s_\lambda^\circ(\mathbf{z}) = \frac{1}{d_\lambda} \mathbf{y}^\top \mathbf{y}.$$

Because \mathbf{R}_λ is a correlation matrix, $\text{tr}(\mathbf{R}_\lambda) = d_\lambda$. Hence

$$\mathbb{E}_{H_0}[\mathbf{y}^\top \mathbf{y}] = \text{tr}(\mathbf{R}_\lambda) = d_\lambda,$$

so

$$\mathbb{E}_{H_0}[s_\lambda^\circ] = 1.$$

Under H_1 ,

$$\mathbb{E}_{H_1}[\mathbf{y}^\top \mathbf{y}] = \text{tr}(\mathbf{R}_\lambda) + \boldsymbol{\delta}_\lambda^\top \boldsymbol{\delta}_\lambda = d_\lambda + \kappa_\lambda,$$

where

$$\kappa_\lambda = \boldsymbol{\Delta}_\lambda^\top \mathbf{D}_\lambda^{-1} \boldsymbol{\Delta}_\lambda = \boldsymbol{\delta}_\lambda^\top \boldsymbol{\delta}_\lambda.$$

Therefore

$$\mathbb{E}_{H_1}[s_\lambda^\circ] = 1 + \frac{\kappa_\lambda}{d_\lambda}.$$

For a Gaussian quadratic form $\mathbf{y}^\top \mathbf{A} \mathbf{y}$ with $\mathbf{A} = \mathbf{I}$, the variance satisfies

$$\text{Var}(\mathbf{y}^\top \mathbf{y}) = 2 \text{tr}(\mathbf{R}_\lambda^2) + 4 \boldsymbol{\delta}_\lambda^\top \mathbf{R}_\lambda \boldsymbol{\delta}_\lambda,$$

with the second term absent under H_0 . Dividing by d_λ^2 gives

$$\text{Var}_{H_0}(s_\lambda^\circ) = \frac{2}{d_\lambda^2} \text{tr}(\mathbf{R}_\lambda^2),$$

and

$$\text{Var}_{H_1}(s_\lambda^\circ) = \frac{2}{d_\lambda^2} \text{tr}(\mathbf{R}_\lambda^2) + \frac{4}{d_\lambda^2} \boldsymbol{\delta}_\lambda^\top \mathbf{R}_\lambda \boldsymbol{\delta}_\lambda.$$

Finally, apply Cantelli's inequality under H_1 to the random variable s_λ° . For any $\tau < \mathbb{E}_{H_1}[s_\lambda^\circ]$,

$$\Pr_{H_1}[s_\lambda^\circ \leq \tau] \leq \frac{\text{Var}_{H_1}(s_\lambda^\circ)}{\text{Var}_{H_1}(s_\lambda^\circ) + (\mathbb{E}_{H_1}[s_\lambda^\circ] - \tau)^2}.$$

Taking complements and substituting the mean gives

$$\Pr_{H_1}[s_\lambda^\circ > \tau] \geq 1 - \frac{\text{Var}_{H_1}(s_\lambda^\circ)}{\text{Var}_{H_1}(s_\lambda^\circ) + (1 + \kappa_\lambda/d_\lambda - \tau)^2}.$$

This proves the theorem. \square

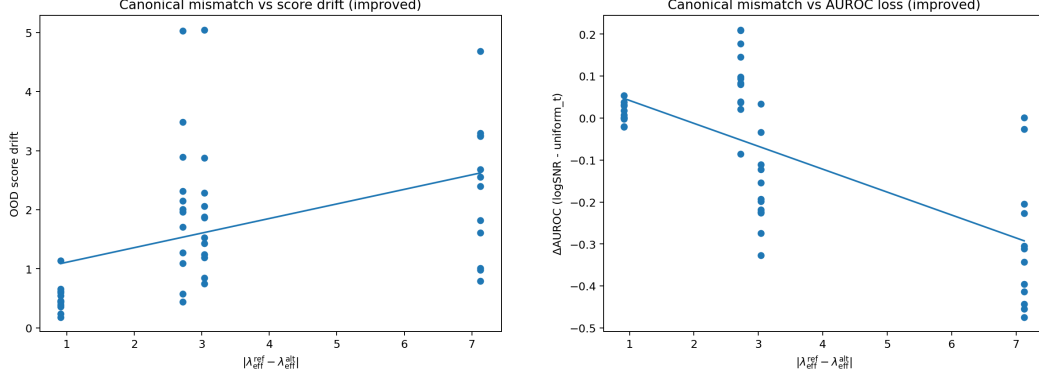

Figure 2: **Canonical-level matching sanity check on improved-diffusion.** **Left:** standardized score drift versus effective logSNR mismatch $|\lambda_{\text{ref}} - \lambda_t|$. **Right:** AUROC degradation relative to the matched logSNR policy. Large mismatches can induce score drift and degrade AUROC, supporting logSNR matching as an implementation requirement rather than a cosmetic alignment choice.

B.6 Canonical-level matching sanity check

This diagnostic tests the implementation role of canonical logSNR matching. For a discrete backbone, a requested canonical level λ_{ref} must be mapped to a native timestep t , whose effective logSNR can be different from λ_{ref} and is denoted by λ_t .

The following simple bound explains why such mismatches can matter: if the internal descriptor and the resulting slot score vary smoothly with the canonical level, then the logSNR mismatch induces controlled score drift.

Fix a selected hook h . Assume that, on the evaluation domain \mathcal{X} , the pooled descriptor $\mathbf{z}_{\cdot, h}(\mathbf{x})$ is L_h -Lipschitz in the canonical level:

$$\|\mathbf{z}_{\lambda, h}(\mathbf{x}) - \mathbf{z}_{\lambda', h}(\mathbf{x})\|_2 \leq L_h |\lambda - \lambda'|, \quad \forall \mathbf{x} \in \mathcal{X}, \lambda \text{ and } \lambda' \text{ two corruption levels.}$$

Assume also that the corresponding oracle slot score $s_{\cdot, h}^\circ$ is M_h -Lipschitz in its feature argument over the attained range. Then

$$|s_{\lambda, h}^\circ(\mathbf{x}) - s_{\lambda', h}^\circ(\mathbf{x})| \leq M_h L_h |\lambda - \lambda'|.$$

Consequently, for a discrete backbone using a native matched level λ_t and a requested canonical level λ_{ref} , by averaging these bounds over the selected hooks in the oracle CFS score :

$$|S_{\text{CFS}, \lambda_{\text{ref}}}^\circ(\mathbf{x}) - S_{\text{CFS}, \lambda_t}^\circ(\mathbf{x})| \leq \frac{1}{|\mathcal{S}|} \sum_{h \in \mathcal{S}} M_h L_h |\lambda_{\text{ref}} - \lambda_t|.$$

The same reasoning can be applied to AUROC score difference.

This diagnostic is only meaningful for discrete backbones (it is detailed in Appendix C.4), so we report it on improved-diffusion. Figure 2 shows two complementary views. First, larger effective canonical mismatches tend to induce larger OOD score drift. Second, sufficiently large mismatches can also produce measurable AUROC degradation relative to the matched logSNR-uniform reference policy. The relation is not perfectly linear, which is expected under discrete timestep collisions and pair-dependent difficulty, but the global trend supports the role of canonical logSNR matching as a genuine methodological requirement rather than a cosmetic alignment choice.

B.7 Empirical diagnostic protocol

The theory of Section 4 yields two measurable quantities used in our empirical diagnostics: the diagonal noncentrality $\hat{\kappa}_\lambda(\mathcal{S})$ and the content-to-instability ratio $\hat{R}_h(\lambda)$. These quantities are estimated on held-out data and compared directly against downstream OOD performance.

For $\hat{\kappa}_\lambda(\mathcal{S})$, we study rank correlation with pairwise AUROC across candidate sparse probes and ID \rightarrow OOD pairs. This diagnostic is summarized in the main paper through Table 3, with representative

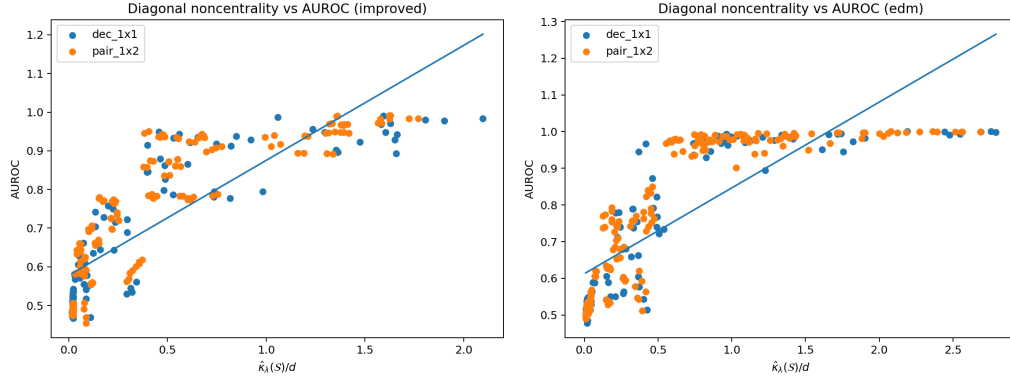

Figure 3: **Empirical validation of diagonal separation.** The estimated diagonal noncentrality $\hat{\kappa}_\lambda(\mathcal{S})/d$ is strongly aligned with downstream AUROC on both improved-diffusion and EDM backbones.

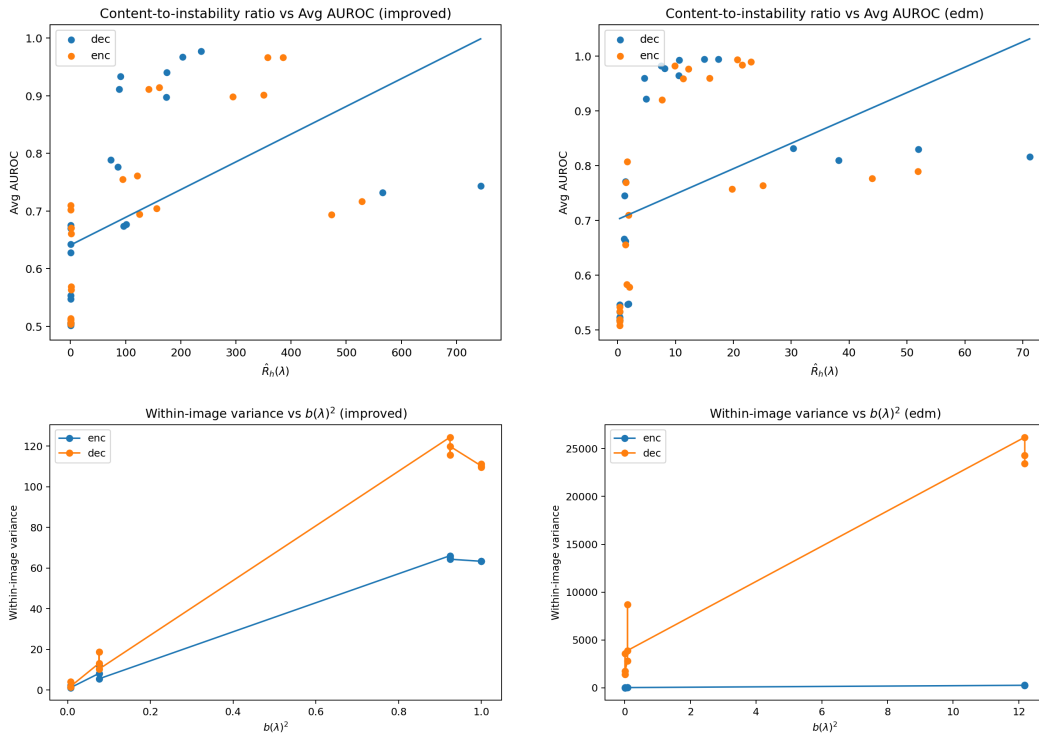

Figure 4: **Empirical validation of low-noise stability and the content-to-instability diagnostic.** **Top row:** $\hat{R}_h(\lambda)$ versus downstream Avg AUROC across candidate hooks for improved-diffusion (left) and EDM (right). **Bottom row:** within-image corruption variance versus $b(\lambda)^2$ for the selected encoder and decoder hooks on improved-diffusion (left) and EDM (right). Across both backbone families, larger content-to-instability ratios align with stronger downstream performance, and lower-noise canonical probing reduces corruption-induced variability.

scatter plots deferred to Figure 3. It confirms this prediction on both improved-diffusion and EDM backbones. Across candidate sparse probes and ID \rightarrow OOD pairs, larger values of $\hat{\kappa}_\lambda(\mathcal{S})/d$ are strongly aligned with larger AUROC, supporting the interpretation of the diagonal score as a structured local detector rather than as an arbitrary lightweight classifier.

For $\hat{R}_h(\lambda)$, we study rank correlation with average AUROC across candidate hooks, and we additionally measure within-image corruption variance as a function of $b(\lambda)^2$. These validations are reported in Figure 4.

B.8 Interpretation

Taken together, the appendix theory supports three concrete conclusions about sparse diffusion probing.

First, the paired encoder-decoder separation decomposes into a decoder term plus a nonnegative conditional encoder residual. This supports using a late decoder snapshot as the primary sparse probe, while interpreting encoder snapshots as complementary rather than primary. Second, the diagonal CFS score is governed by a measurable diagonal noncentrality parameter κ_λ , so the score can be analyzed as a structured local detector rather than as an arbitrary lightweight head. Third, low-noise canonical probing reduces corruption-induced instability: under a local smoothness approximation, within-image feature variance scales as $b(\lambda)^2$, and the empirical content-to-instability diagnostic captures this effect.

When included, the canonical-matching diagnostic further supports that logSNR alignment is not merely a bookkeeping device: large discrete-level mismatches can induce score drift and degrade AUROC.

The theory remains local rather than universal. It does not claim that sparse internal probing dominates every conceivable output-space detector. Its purpose is narrower: to explain and predict which sparse internal probes should work best under a backbone-equated protocol.

C Experimental Protocols, Splits, and Canonicalization

This section groups the protocol elements shared across methods: dataset splits, canonical level construction, backbone-specific corruption mappings, adapter outputs, and logical cost accounting.

C.1 Small-scale benchmark protocol

The small-scale benchmark uses the three ID datasets

$$\mathcal{I}_{\text{small}} = \{\text{CIFAR-10, SVHN, CelebA32}\},$$

and the OOD pool

$$\mathcal{O}_{\text{small}} = \{\text{CIFAR-10, SVHN, CelebA32, CIFAR-100, DTD}\}.$$

For each ID dataset, all remaining datasets in the pool are treated as OOD, producing 12 ID→OOD pairs per backbone.

For each ID dataset, we define:

- an ID-fit split used to fit ID-only statistics and density heads;
- an ID-test split used for in-distribution evaluation;
- external OOD-test splits for all OOD datasets.

These splits are fixed and shared across methods.

Relative-OOD interpretation. Let P_\star denote the training distribution of the frozen checkpoint, and let P denote the chosen evaluation ID dataset. Our detector should be interpreted as performing OOD detection *relative to the evaluation reference bank* P , not as an absolute test of membership in P_\star . This distinction is especially important in cross-source or transfer settings.

C.2 ImageNet200 / ImageNet1K protocol

ImageNet200 and ImageNet1K are used as checkpoint-controlled large-scale benchmarks under a single official ImageNet-64 improved-diffusion backbone. Since the official training split is not used in our setup, we adopt deterministic disjoint val-only protocols. For ImageNet200, we use a class-stratified split of the validation set into:

- **ID-fit / bank split:** used to fit ID statistics;
- **ID-test split:** the complementary subset used for in-distribution evaluation.

For ImageNet1K, we use the same val-only deterministic split policy to define ID-fit and ID-test subsets.

In both benchmarks, the OOD suite contains two near-OOD sets, **NINCO** and **SSB-hard**, together with one far-OOD texture-shift set, **Textures**.

Checkpoint-controlled protocol. All large-scale results in this appendix use the same official ImageNet-64 improved-diffusion checkpoint (imagenet64_uncond_100M_1500K.pt). This removes cross-family variability and isolates method differences under a single shared-source backbone.

C.3 Canonical level construction: K_{grid} vs. K_c

Purpose. Discrete backbones require mapping continuous canonical levels to discrete timesteps, which may produce duplicates. We separate:

- K_{grid} : candidate grid resolution used to build a dense set of possible canonical levels;
- K_c : number of selected levels actually used by the method.

Construction. We construct a candidate grid

$$\{\lambda_i^{\text{grid}}\}_{i=1}^{K_{\text{grid}}} \subset [\lambda_{\min}, \lambda_{\max}].$$

For discrete backbones, each candidate level is mapped to the nearest available timestep in logSNR space. When `unique=true`, repeated timestep assignments are removed, and the final selected set contains at most K_c distinct levels. For continuous backbones, the selected levels are evenly spaced directly in canonical space.

Interpretation. Increasing K_{grid} improves mapping fidelity on discrete backbones without necessarily increasing test-time cost, because only the final selected K_c levels are used downstream.

Remark 1. *The separation between K_{grid} and K_c is important for fair backbone matching: selection fidelity and evaluation cost should not be conflated.*

C.4 Backbone-specific realization of canonical corruption

C.4.1 Improved-diffusion (VP-DDPM)

For improved-diffusion checkpoints, the native forward corruption process is

$$\mathbf{x}_t = \sqrt{\bar{\alpha}_t} \mathbf{x}_0 + \sqrt{1 - \bar{\alpha}_t} \boldsymbol{\varepsilon}, \quad \boldsymbol{\varepsilon} \sim \mathcal{N}(\mathbf{0}, \mathbf{I}),$$

where $\bar{\alpha}_t$ is the cumulative noise-schedule coefficient of the checkpoint.

Hence, the corresponding corruption coefficients in the shared canonical form

$$\mathbf{x}_\lambda = a(\lambda) \mathbf{x}_0 + b(\lambda) \boldsymbol{\varepsilon},$$

are

$$a_t = \sqrt{\bar{\alpha}_t}, \quad b_t = \sqrt{1 - \bar{\alpha}_t},$$

and the induced discrete canonical logSNR is

$$\lambda_t = \log \frac{\bar{\alpha}_t}{1 - \bar{\alpha}_t}.$$

A desired canonical level λ is therefore mapped to the nearest native timestep in logSNR space:

$$t(\lambda) = \arg \min_t |\lambda_t - \lambda|.$$

When several candidate canonical levels map to the same native timestep, duplicates are removed by the unique-level construction described in Appendix C.3.

C.4.2 EDM family

EDM-style models expose a continuous noise variable, but the exact native parameterization depends on the checkpoint preconditioning family. Rather than matching checkpoints through their native interface directly, we canonicalize them through the effective corruption ratio

$$\tilde{\sigma}(\lambda) := \frac{b(\lambda)}{a(\lambda)} = \exp(-\lambda/2),$$

which follows from

$$\lambda = \log \frac{a(\lambda)^2}{b(\lambda)^2}.$$

The adapter, therefore, maps each canonical level λ to the checkpoint-specific model input corresponding to the same effective ratio $\tilde{\sigma}(\lambda)$, and returns coefficients (a, b) such that

$$\mathbf{x}_\lambda = a \mathbf{x}_0 + b \boldsymbol{\varepsilon}.$$

Different EDM-family preconditionings may realize the same $\tilde{\sigma}$ with different coefficient pairs (a, b) . For example, a VE/EDM-style realization uses

$$a = 1, \quad b = \tilde{\sigma},$$

whereas a VP-style realization can be written as

$$a = (1 + \tilde{\sigma}^2)^{-1/2}, \quad b = \tilde{\sigma}(1 + \tilde{\sigma}^2)^{-1/2}.$$

In both cases,

$$\frac{b}{a} = \tilde{\sigma},$$

so the same canonical λ corresponds to the same effective corruption strength even though the native checkpoint interface differs.

C.4.3 Shared canonical semantics

Although improved-diffusion and EDM differ in interface and preconditioning, all methods operate through the same canonical corruption abstraction. This allows meaningful cross-backbone comparisons at matched canonical levels.

C.5 Shared adapter outputs and reconstruction rules

All harmonized methods are routed through a shared adapter layer. At each canonical level, the adapter provides:

- a denoised estimate $\hat{\mathbf{x}}_0$,
- optional access to intermediate activations,
- and, when needed, an $\hat{\boldsymbol{\varepsilon}}$ estimate recovered through

$$\hat{\boldsymbol{\varepsilon}} = \frac{\mathbf{x} - a \hat{\mathbf{x}}_0}{b}. \quad (11)$$

This ensures that all output-space baselines and internal-feature methods use a compatible corruption semantics, regardless of the native output conventions of the original implementation.

C.6 Implementation details specific to CFS

The conceptual design of CFS is described in Section 4. Here we report only implementation-level details needed for exact reproduction.

C.6.1 Admissible hook search and shortlist size

A candidate hook is admissible only if a dry forward pass returns a 4D tensor of shape $B \times C \times H \times W$. In practice, we restrict the search to stage-level encoder and decoder blocks and keep a small shortlist within each structural region before applying the ID-only proxy. For every experiment, we report:

- the number of admissible encoder candidates,
- the number of admissible decoder candidates,
- the shortlist size retained in each region,
- the final selected encoder and decoder module names.

C.6.2 ID-only probe configuration

The proxy uses a small ID-only probe set. For exact reproducibility, we report:

- the number of ID probe images,
- the number of corruption repeats per image,
- whether the same noise draw is reused across canonical levels,

C.6.3 Exact pooled-slot construction

For each retained slot, we apply channel-wise spatial mean and standard deviation pooling, yielding a descriptor of dimension $2C_{k,\ell}$. We report, for each backbone family and benchmark:

- the selected canonical levels,
- the selected encoder and decoder block names,
- the resulting feature-map shapes,
- the pooled descriptor dimensions.

C.6.4 Diagonal score details

Each pooled slot is modeled independently with ID-only diagonal statistics. For exact reproduction, we report:

- whether the slot features are standardized before fitting,
- whether slot scores are averaged uniformly or reweighted.

D Implementation Taxonomy and Baseline Specifications

D.1 Implementation taxonomy

We implement these methods to preserve the core probe and score logic of the original method while routing it through our shared adapter and canonicalization pipeline.

Methods in this paper.

- MSMA: harmonized faithful port;
- DIFFPATH: harmonized faithful port;
- DDPM-OOD: harmonized faithful port;
- GEPC: harmonized faithful port;
- CFS: proposed internal representation-space method.

Methods discussed but not retained in the strict main benchmark. We position SCOPED and EigenScore conceptually in related work, but do not include them in the strict main MBE table. In our attempts, we did not obtain a controlled, harmonized rerun of SCOPED suitable for the shared benchmark. EigenScore was also not retained because matched reruns within the shared adapter/canonicalization pipeline were substantially heavier, and some public checkpoint/artifact combinations did not yield reliable runs. We therefore restrict the strict main benchmark to methods for which we can provide controlled backbone-equated evaluation under matched corruption semantics and budget accounting.

Official repositories used as starting points. When available, our harmonized implementations were initialized from the official public repositories of the corresponding methods: MSMA¹, Diff-Path², DDPM-OOD³, and GEPC⁴. These repositories were then adapted to the shared adapter, canonicalization, and logical-budget interface of MBE.

D.2 Common harmonized interface

All baselines are evaluated through the same adapter interface, the same input normalization to $[-1, 1]$, and the same canonical corruption semantics. For a selected canonical level λ_k with coefficients (a_k, b_k) , we explicitly corrupt the clean image as

$$\mathbf{x}_k = a_k \mathbf{x}_0 + b_k \boldsymbol{\varepsilon}, \quad \boldsymbol{\varepsilon} \sim \mathcal{N}(\mathbf{0}, \mathbf{I}).$$

From the frozen backbone, we then recover native denoising quantities $\hat{\mathbf{x}}_{0,k}$ and $\hat{\boldsymbol{\varepsilon}}_k$. For improved-diffusion backbones, $\hat{\boldsymbol{\varepsilon}}_k$ is extracted natively from the model output using the correct timestep scaling and mean-parameterization conventions, and $\hat{\mathbf{x}}_{0,k}$ is recovered from the same forward pass. For EDM-style backbones, the adapter returns $\hat{\mathbf{x}}_{0,k}$ through one denoising call and reconstructs

$$\hat{\boldsymbol{\varepsilon}}_k = \frac{\mathbf{x}_k - a_k \hat{\mathbf{x}}_{0,k}}{b_k}.$$

Thus, one backbone evaluation at one level counts as one logical forward pass, even if both $\hat{\mathbf{x}}_0$ and $\hat{\boldsymbol{\varepsilon}}$ are recovered from that same call.

D.3 MSMA (harmonized faithful port)

MSMA is the closest baseline in our suite to a harmonized faithful port. Its core logic is preserved: build a multiscale descriptor from denoiser-derived quantities across K_c levels, then fit an ID-only density head on the resulting feature vectors.

Feature construction. For each canonical level λ_k , we compute

$$f_k(\mathbf{x}_0) = \|\hat{\boldsymbol{\varepsilon}}_k\|_2,$$

where $\hat{\boldsymbol{\varepsilon}}_k$ is obtained through the shared native adapter interface. The final multiscale descriptor is

$$F(\mathbf{x}_0) = [f_1(\mathbf{x}_0), \dots, f_{K_c}(\mathbf{x}_0)] \in \mathbb{R}^{K_c}.$$

Head and scoring. We fit an ID-only density model on $F(x)$, after optional feature standardization. Our implementation supports:

- a diagonal Gaussian head,
- a Gaussian mixture model (GMM),
- a k -nearest-neighbor distance head.

The final score is always OOD-high: negative log-likelihood for Gaussian/GMM heads, or distance for the KNN head.

¹<https://github.com/ahsanMah/msma>

²<https://github.com/clear-nus/diffpath>

³<https://github.com/marksgraham/ddpm-ood>

⁴<https://github.com/RouzAY/gepc-diffusion>

What is preserved and what is adapted. The preserved part is the multiscale descriptor and the density score. The adapted part is the use of a common adapter interface, canonical logSNR levels, and a shared improved/EDM implementation.

D.4 DiffPath (harmonized faithful port)

DiffPath is implemented as a faithful port for path-based diffusion OOD detection. Rather than reproducing a native implementation verbatim, we preserve the key idea: summarize a *multilevel denoising path* and fit an ID-only density model on the resulting path statistics.

Recursive path construction. Levels are ordered from clean to noisy. We initialize

$$\mathbf{x}_1 = a_1 \mathbf{x}_0 + b_1 \boldsymbol{\varepsilon},$$

and for each level k compute $(\hat{\mathbf{x}}_{0,k}, \hat{\boldsymbol{\varepsilon}}_k)$ from the current state \mathbf{x}_k . A scalar path statistic q_k is then extracted from $\hat{\boldsymbol{\varepsilon}}_k$ using one of the following reductions:

$$q_k \in \left\{ \text{mean}(\hat{\boldsymbol{\varepsilon}}_k), \text{mean}(|\hat{\boldsymbol{\varepsilon}}_k|), \text{mean}(\hat{\boldsymbol{\varepsilon}}_k^2) \right\}.$$

We then propagate the path recursively:

$$\mathbf{x}_{k+1} = a_{k+1} \hat{\mathbf{x}}_{0,k} + b_{k+1} \hat{\boldsymbol{\varepsilon}}_k.$$

Feature variants. We use two harmonized feature families. The 1D variant computes

$$\phi_{1d}(x) = \sqrt{\frac{1}{K_c - 1} \sum_{k=1}^{K_c-1} \left(\frac{q_{k+1} - q_k}{\Delta \lambda_k} \right)^2},$$

The 6D variant computes low-order moments of both the path values $Q = (q_1, \dots, q_{K_c})$ and their level-wise differences $\Delta Q = (q_2 - q_1, \dots, q_{K_c} - q_{K_c-1})$:

$$\phi_{6d}(x) = [\text{mean}(Q), \text{mean}(Q^2), \|Q\|_3, \text{mean}(|\Delta Q|), \text{mean}((\Delta Q)^2), \|\Delta Q\|_3].$$

Head and scoring. We fit either a 1D KDE for the 1D feature or a diagonal Gaussian model for the 6D feature. Scores are OOD-high via negative log-density.

D.5 DDPM-OOD (harmonized faithful port)

Our DDPM-OOD baseline is implemented as a harmonized *multi-start reconstruction*. It preserves the main scoring logic of DDPM-OOD: reconstruction error should be evaluated from several noisy starting points, normalized using ID statistics *per start*, and then aggregated into a single OOD score.

Canonical reverse schedule and starting points. We first build a canonical level set

$$\lambda_1 > \lambda_2 > \dots > \lambda_{K_c},$$

ordered from clean to noisy, and reverse it into a noisy-to-clean reconstruction schedule. A subset of starting points is then selected by subsampling this reverse schedule.

Multi-start reconstruction. For a selected starting level $\lambda^{(s)}$, we generate

$$\mathbf{x}_s = a_s \mathbf{x}_0 + b_s \boldsymbol{\varepsilon}, \quad \boldsymbol{\varepsilon} \sim \mathcal{N}(\mathbf{0}, \mathbf{I}),$$

and reconstruct deterministically along the corresponding reverse suffix. If the suffix levels are denoted

$$\lambda^{(s)} = \lambda_{j_1}, \lambda_{j_2}, \dots, \lambda_{j_m},$$

then at each step, we compute $(\hat{\mathbf{x}}_{0,j_r}, \hat{\boldsymbol{\varepsilon}}_{j_r})$ from the current state and propagate toward the next cleaner canonical level:

$$\mathbf{x}_{j_{r+1}} = a_{j_{r+1}} \hat{\mathbf{x}}_{0,j_r} + b_{j_{r+1}} \hat{\boldsymbol{\varepsilon}}_{j_r}.$$

The final clean reconstruction is the terminal $\hat{\mathbf{x}}_0$ at the end of the suffix.

Per-start reconstruction errors and ID normalization. For each start s , we compute the reconstruction error

$$m_s(\mathbf{x}_0) = \frac{1}{d} \|\hat{\mathbf{x}}_{0,s} - \mathbf{x}_0\|_2^2.$$

This yields a vector of per-start errors

$$M(\mathbf{x}_0) = [m_1(\mathbf{x}_0), \dots, m_S(\mathbf{x}_0)].$$

For each start s , we fit ID-only normalization statistics and form

$$z_s(\mathbf{x}) = \frac{m_s(\mathbf{x}) - c_s}{\sigma_s}.$$

Aggregation. The final scalar score is obtained by aggregating the per-start normalized deviations:

$$S(\mathbf{x}) = \text{Agg}(z_1(\mathbf{x}), \dots, z_S(\mathbf{x})),$$

where Agg denotes mean, median, or sum.

D.6 GEPC (harmonized faithful port)

Our GEPC baseline is implemented as a MBE-adapted output-consistency faithful port. The central idea is preserved: if the denoiser behaves approximately equivariantly under a small discrete transformation group, then in-distribution inputs should exhibit stronger posterior consistency than OOD inputs.

Canonical corruption and transformed outputs. For each selected canonical level λ_k , we first form

$$\mathbf{x}_k = a_k \mathbf{x}_0 + b_k \boldsymbol{\varepsilon}, \quad \boldsymbol{\varepsilon} \sim \mathcal{N}(\mathbf{0}, \mathbf{I}),$$

then evaluate the denoiser on both \mathbf{x}_k and transformed copies $g \cdot \mathbf{x}_k$, where g belongs to a small discrete group such as flips or 180° rotation. From each output we recover $\hat{\mathbf{x}}_{0,k}$ and $\hat{\boldsymbol{\varepsilon}}_k$, and build the score proxy

$$\hat{\mathbf{s}}_k = -\frac{\hat{\boldsymbol{\varepsilon}}_k}{b_k}.$$

Consistency features. We compare the reference output to the transformed-and-brought-back outputs $g^{-1} \cdot \hat{\mathbf{s}}_k(g \cdot \mathbf{x}_k)$ and $g^{-1} \cdot \hat{\mathbf{x}}_{0,k}(g \cdot \mathbf{x}_k)$. This yields several OOD-high consistency features, including a normalized score discrepancy, a cosine consistency score, and a normalized $\hat{\mathbf{x}}_0$ -consistency score.

Level-wise calibration and aggregation. At each level, these raw consistency features are calibrated with an ID-only head, typically KDE or z-score normalization. Feature scores are then aggregated within each level, and finally across canonical levels using mean, weighted mean, or trimmed mean aggregation.

E Focused Ablations

We restrict appendix ablations to controls that directly test the paper’s central claim: the gain of CFS comes from *where* the frozen diffusion backbone is probed, rather than from hidden budget, brittle hook choices, or downstream head complexity.

E.1 Pareto budget analysis and budget-matched comparisons

A standard concern in diffusion OOD comparisons is hidden compute. We therefore report a budget-aware comparison in which logical test-time cost is made explicit. The goal is simple: if output-space baselines are given a matched or larger budget, does the representation-space advantage persist?

More precisely, we vary the number of selected canonical levels while keeping Monte Carlo test $\text{MC}_{\text{test}} = 1$, so that the dominant logical cost scales with the number of backbone evaluations. For CFS, $K_c \times K_s$ denotes the number of selected canonical levels and retained stage slots. Since all

Table 6: **Budget-aware comparison under MBE.** We vary the logical test-time budget while keeping $MC_{\text{test}} = 1$. This disentangles representation quality from hidden multilevel accumulation. For CFS, $K_c \times K_s$ denotes the number of selected canonical levels and retained stage slots, respectively. Because all retained hooks at a given canonical level are extracted within the same backbone forward pass, the logical cost depends on K_c only, not on K_s .

Budget (#F/img)	Method	Improved-diffusion		EDM	
		AvgAUROC \uparrow	AvgWorstAUROC \uparrow	AvgAUROC \uparrow	AvgWorstAUROC \uparrow
1	CFS _{enc} ($1 \times 1_{\text{low}}$)	0.849	0.773	0.900	0.805
1	CFS _{dec} ($1 \times 1_{\text{low}}$)	0.886	0.793	0.919	0.809
1	CFS ($1 \times 2_{\text{low}}$)	0.887	0.799	0.916	0.814
1	CFS ($1 \times 2_{\text{high}}$)	0.497	0.492	0.498	0.495
1	CFS _{enc} ($1 \times 1_{\text{high}}$)	0.500	0.496	0.498	0.494
1	CFS _{dec} ($1 \times 1_{\text{high}}$)	0.495	0.486	0.498	0.495
2	CFS ($2 \times 1_{\text{enc}}$)	0.839	0.761	0.880	0.781
2	CFS ($2 \times 1_{\text{dec}}$)	0.853	0.762	0.906	0.800
2	CFS (2×2)	0.868	0.779	0.902	0.804
2	CFS (2×4)	0.873	0.783	0.900	0.794
2	MSMA	0.781	0.652	0.770	0.645
2	DIFFPATH	0.802	0.633	0.778	0.630
4	CFS 4×2	0.843	0.763	0.873	0.791
4	MSMA	0.785	0.669	0.790	0.673
4	DIFFPATH	0.766	0.642	0.787	0.631
8	MSMA	0.779	0.675	0.798	0.682
8	DIFFPATH	0.779	0.640	0.792	0.634

retained hooks at a given level are extracted in the same forward pass, logical cost depends on K_c , not on K_s .

Table 6 shows that the best one-forward operating points are already sparse CFS variants. In particular, CFS_{dec}($1 \times 1_{\text{low}}$) and CFS($1 \times 2_{\text{low}}$) dominate budget-matched output-space baselines while using only one backbone evaluation per image. Richer CFS variants improve representation size without changing the backbone cost at fixed K_c , but the gains beyond the strongest one-forward operating points are modest. The key conclusion is therefore not merely that CFS is accurate, but that its gain does not come from hidden multilevel accumulation.

E.2 Hook-pair robustness and proxy validation

A natural concern is that the encoder-decoder pair selected by CFS(1×2) could be fragile or cherry-picked. To test this, we evaluate multiple admissible encoder and decoder candidates within the same structural regions and report (i) the pairwise performance landscape, (ii) the relation between the ID-side pair proxy and final pair performance, and (iii) a complementary region-wise proxy validation. All results are computed at the fixed low-noise canonical level used in the main paper.

Figure 5 supports robustness more strongly than exact pair recovery. For the improved backbone, the landscape is structured rather than spiky: the proxy-selected pair reaches 0.886 Avg AUROC, versus 0.895 for the oracle admissible pair, so the proxy lands in the correct high-performing basin even without identifying the exact optimum. For EDM, the heatmap is flatter, and the main conclusion is different: several nearby pairs perform similarly well, so the method is not driven by a single brittle choice.

Table 7 shows that, on improved-diffusion, the proxy is more informative on the decoder side than on the encoder side, matching the stronger decoder-column structure in the heatmap. On EDM, the proxy is weaker as a regional ranker, but the oracle gaps remain small. Overall, the selection rule does not need to find the exact best pair; it only needs to place CFS(1×2) in a stable, high-performing part of the network without exhaustive search.

E.3 Canonical-level robustness

The main paper identifies low-noise canonical probing as the strongest operating regime. We now test whether this effect reflects a stable region or a narrowly tuned choice of canonical level.

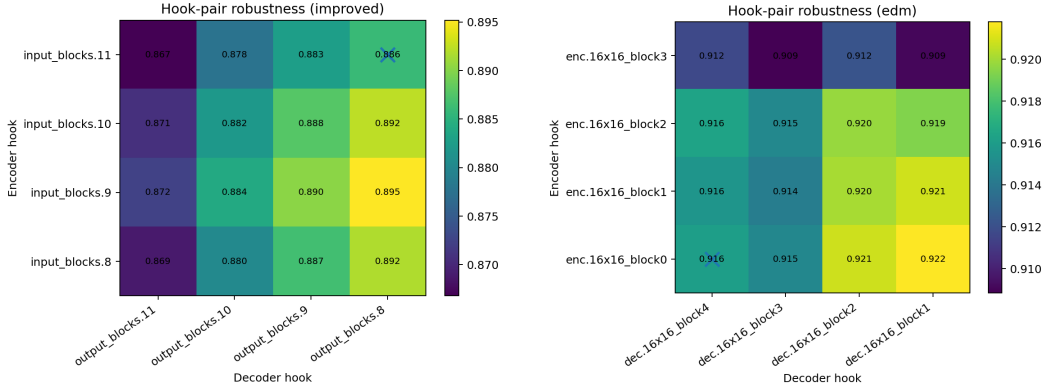

Figure 5: **Corresponding hook-pair heatmaps for CFS(1×2)**. Each cell reports the Avg AUROC of one admissible pair at the low-noise canonical level used in the main paper. The marker denotes the final pair obtained from the ID-side proxy shortlist. For the improved backbone, the selected pair falls in the same high-performing basin as the oracle pair. For EDM, the dominant pattern is a broad plateau of strong pairs, indicating low sensitivity to the exact hook choice even when the proxy is less predictive.

Table 7: **Region-wise proxy-selected modules versus empirical oracle modules for CFS(1×2)**. For each backbone and region, we compare the downstream AvgAUROC obtained with the proxy-selected module to that obtained with the best admissible module in hindsight, while keeping the opposite region fixed to its proxy-selected choice. Small gaps indicate that the proxy-selected module lies close to the empirical oracle without using any OOD labels.

Backbone	Region	Proxy-selected AvgAUROC \uparrow	Oracle AvgAUROC \uparrow	Gap \downarrow
Improved-diffusion	Encoder	0.8861	0.8952	0.0091
Improved-diffusion	Decoder	0.8861	0.8861	0.0000
EDM	Encoder	0.9161	0.9163	0.0002
EDM	Decoder	0.9161	0.9218	0.0057

Since the final method uses single-level variants, we sweep the canonical level λ and evaluate two representative detectors: $\text{CFS}_{\text{dec}}(1 \times 1)$ and $\text{CFS}(1 \times 2)$. The key question is whether performance remains strong over a neighborhood of low-noise levels, rather than peaking at a single hand-picked value.

Figure 6 shows the same qualitative pattern on both backbones. For strongly negative λ , both detectors remain close to chance, indicating that highly corrupted canonical levels are not useful. Performance then rises rapidly as λ moves toward lower-noise regimes, before flattening into a broad plateau for positive λ . Thus, the benefit of low-noise probing is not confined to one operating point.

There are, however, mild backbone-specific differences. On improved-diffusion, $\text{CFS}(1 \times 2)$ is most helpful in the transition regime, whereas on the final high- λ plateau the gap to decoder-only probing becomes small. EDM shows an even flatter plateau once λ becomes positive. Overall, the sweeps suggest that the canonical level is the primary driver, whereas richer representation composition mainly improves the intermediate regime and worst-case robustness.

E.4 CFS family analysis

The role of representation composition is already visible in the budget-matched rows of Table 6, so we do not duplicate those results. At fixed logical cost, the comparison between $\text{CFS}(2 \times 1_{\text{enc}})$, $\text{CFS}(2 \times 1_{\text{dec}})$, and $\text{CFS}(2 \times 2)$ shows how performance changes when using encoder-only, decoder-only, or combined encoder-decoder snapshots across two canonical levels.

Decoder-only probing already captures most of the gain once the canonical level reaches the strong low-noise regime. Encoder-decoder composition is most useful before the final plateau is reached and for worst-case robustness. The main claim is therefore not that composition is always necessary, but that it provides a meaningful robustness margin beyond an already strong decoder-only baseline.

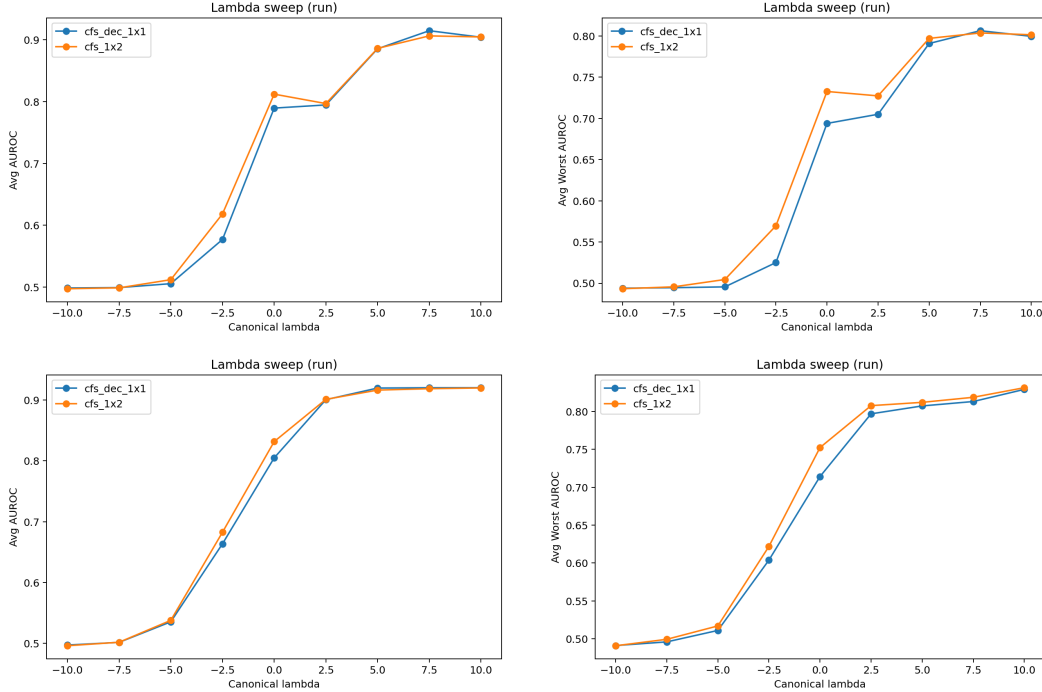

Figure 6: **Canonical-level robustness for single-level CFS variants.** **Top:** improved-diffusion backbone. **Bottom:** EDM backbone. **Left:** AvgAUROC. **Right:** AvgWorstAUROC. Across both backbones, performance is near chance for strongly negative λ , rises sharply through the intermediate regime, and then enters a broad high-performing plateau at positive λ . This supports the claim that the low-noise advantage is robust rather than tied to a single finely tuned canonical level.

Table 8: **Pooling rule ablation for CFS(1×2).** We report both backbone families separately to test whether the gain of the primary detector relies only on first-order channel averages or also on within-channel dispersion captured by standard deviation pooling.

Pooling	Improved-diffusion		EDM	
	AvgAUROC \uparrow	AvgWorstAUROC \uparrow	AvgAUROC \uparrow	AvgWorstAUROC \uparrow
Mean only	0.8645	0.7785	0.9078	0.8150
Std only	0.8684	0.7381	0.9047	0.7693
Mean + Std	0.8870	0.7990	0.9160	0.8140

E.5 Pooling rule

We compare mean-only, std-only, and mean+std pooling for CFS(1×2). This tests whether first-order channel averages suffice or whether within-channel dispersion carries additional useful signal once both encoder and decoder snapshots are retained. Results are presented in Table 8.

Combining mean and standard-deviation pooling is clearly beneficial on improved-diffusion, where it gives the best average and worst-case performance. On EDM, mean+std gives the best average AUROC, while mean-only is marginally better in AvgWorstAUROC. Overall, dispersion features help the main operating point, but their gain is not perfectly uniform across criteria.

E.6 Diagonal score versus alternative ID-only scores

The main paper uses a lightweight diagonal score so that the comparison stays focused on representation quality rather than downstream classifier capacity. We now test whether the strong performance of CFS(1×2) persists under stronger but still ID-only scores.

Table 9 shows that the sparse CFS(1×2) representation remains strong across several ID-only heads, which supports the view that the main signal comes from the selected features rather than from a

Table 9: **Head sensitivity under the same sparse representation for CFS(1×2)**. We report both backbone families separately. The goal is to test whether the usefulness of the primary detector comes mainly from the selected representation rather than from a particular downstream head.

Head	Improved-diffusion		EDM	
	AvgAUROC ↑	AvgWorstAUROC ↑	AvgAUROC ↑	AvgWorstAUROC ↑
Diagonal (main paper)	<u>0.8861</u>	0.7973	0.9161	0.8122
Shrinkage covariance	0.8763	<u>0.8234</u>	<u>0.9207</u>	<u>0.8618</u>
KNN	0.9101	0.8622	0.9501	0.9043
GMM-light	0.8597	0.7838	0.9121	0.7837

Table 10: **Sensitivity to the ID-fit bank size for CFS(1×2)**. Each entry reports the mean over three random seeds. The goal is to assess whether the sparse two-slot representation reaches stable performance with moderate ID-only calibration data.

ID-fit bank size	Improved-diffusion		EDM	
	AvgAUROC ↑	AvgWorstAUROC ↑	AvgAUROC ↑	AvgWorstAUROC ↑
100	0.8873	0.8031	0.9177	0.8207
500	0.8871	0.8006	0.9164	0.8150
1000	0.8863	0.7982	0.9161	0.8117
Full	0.8866	0.7979	0.9164	0.8127

specialized classifier. At the same time, the exact ranking is not head-invariant: KNN is strongest on both backbones, and shrinkage covariance also improves worst-case robustness over the diagonal head.

We therefore interpret the diagonal score as a conservative evaluation choice rather than as the empirically strongest one. Its role in the main paper is to keep the detector lightweight and to avoid conflating feature quality with additional head capacity.

E.7 ID-fit bank size sensitivity

Because CFS(1×2) is calibrated from ID-only reference statistics, practical performance may depend on the size of the ID-fit bank. We therefore vary the number of ID-fit samples used to estimate the slot statistics and report the resulting performance.

Table 10 shows that CFS(1×2) is only weakly sensitive to the ID-fit bank size on both backbones. Even a bank of 100 ID samples already performs very close to the larger-bank regime. There is therefore no evidence that the main operating point depends on an unusually large calibration set.

E.8 Statistical stability across random seeds

Finally, we report repeated runs that vary the stochastic seed in the evaluation pipeline. The goal is not to estimate every source of variance exhaustively, but to check whether the main conclusions remain stable under the stochastic components that most directly affect the reported scores.

Tables 11 and 12 report seed stability for both CFS(1×2) and CFS_{dec}(1×1).

Across both backbones, the standard deviations are tiny, so the observed rankings are highly stable across repeated runs. For improved-diffusion, CFS(1×2) consistently remains slightly stronger than CFS_{dec}(1×1) in both average and worst-case AUROC while also improving FPR95. For EDM, the trade-off is equally stable but slightly different: CFS_{dec}(1×1) retains a small advantage in AvgAUROC and FPR95, whereas CFS(1×2) retains the better AvgWorstAUROC.

E.9 Architecture-transfer sanity check

Although our main experiments use U-Net-style diffusion backbones, CFS only requires access to block-level internal activations at canonical corruption levels. As a sanity check, we apply the same sparse snapshot construction to a transformer-based diffusion backbone, U-ViT. Unlike convolutional U-Nets, U-ViT keeps a token sequence of nearly constant size across its transformer blocks; its

Table 11: **Statistical stability across random seeds on improved-diffusion.** We report mean \pm standard deviation over repeated runs. The very small deviations indicate that the comparison between the two sparse CFS variants is not driven by stochastic fluctuations.

Method	AvgAUROC \uparrow	AvgWorstAUROC \uparrow	FPR95 \downarrow
CFS _{dec} (1 \times 1)	0.88566 \pm 0.00008	0.79103 \pm 0.00015	0.35678 \pm 0.00016
CFS(1 \times 2)	0.88609 \pm 0.00002	0.79721 \pm 0.00003	0.33546 \pm 0.00024

Table 12: **Statistical stability across random seeds on EDM.** We report mean \pm standard deviation over repeated runs. Again, the deviations are extremely small, showing that the reported trade-off between the two sparse CFS variants is stable across seeds.

Method	AvgAUROC \uparrow	AvgWorstAUROC \uparrow	FPR95 \downarrow
CFS _{dec} (1 \times 1)	0.91950 \pm 0.00009	0.80730 \pm 0.00027	0.18149 \pm 0.00021
CFS(1 \times 2)	0.91618 \pm 0.00009	0.81223 \pm 0.00005	0.19132 \pm 0.00012

U-shaped structure comes from input blocks, a middle block, output blocks, and long skip connections rather than from explicit spatial downsampling and upsampling. We therefore replace the U-Net encoder/decoder hook taxonomy by early, middle, and late transformer-block snapshots, and pool token features using channel-wise mean and standard deviation over image tokens.

The purpose is to test whether the sparse-snapshot principle transfers beyond convolutional U-Nets. All runs use the same low-noise canonical level, with target $\lambda = 5.0$, effective $\lambda = 5.0329$, native U-ViT timestep $t = 21$, and $b^2 = 6.48 \times 10^{-3}$. The hooked U-ViT activations have shape $B \times 257 \times 512$, corresponding to 256 image tokens plus one time token; CFS pools the image tokens only. We also include an output-space baseline using the same U-ViT checkpoint and the same canonical level: it scores images by the final reconstruction MSE $\|\hat{\mathbf{x}}_0 - \mathbf{x}_0\|^2$ with an ID-only one-dimensional density fit.

Tables 13 and 14 support the architecture-transfer interpretation: sparse internal snapshots remain informative even when spatial U-Net feature maps are replaced by token-level transformer states. Importantly, the gain does not come merely from using a low-noise U-ViT forward: the output reconstruction baseline reaches only 0.778 AvgAUROC and 0.653 AvgFPR95, whereas CFS-late improves to 0.891 AvgAUROC and 0.213 AvgFPR95 at the same one-forward cost. The paired early+late variant slightly improves AvgAUROC, while the late snapshot gives the best AvgFPR95, suggesting that late transformer blocks already concentrate most of the useful signal in this setting. We emphasize that this result should not be read as a new U-ViT OOD benchmark: performance is not uniform across all source datasets, and the CIFAR-10-as-ID case remains the main failure mode.

F Extended CIFAR-Scale Results

This section provides the full pairwise breakdown behind the compact summaries shown in the main paper. Its role is descriptive rather than argumentative: it exposes where the main representation-space advantage comes from, pair by pair, under the same controlled protocol.

We begin with the full pairwise breakdown for the primary shared-source benchmark, i.e. the CIFAR10-source checkpoint family used in the main paper. Tables 15 and 16 report AUROC and FPR95 for all ID \rightarrow OOD pairs. To keep the appendix readable, we expose pairwise operating-point behavior mainly for the two main sparse variants, CFS_{dec}(1 \times 1) and CFS(1 \times 2).

The full tables make two patterns clear. First, the main-paper summaries are not driven by one isolated pair: the sparse CFS variants are strong across a broad set of ID \rightarrow OOD configurations, especially on compact IDs and texture-driven shifts. Second, the decoder-only and paired encoder-decoder variants remain very close on many pairs, which reinforces the compression result already visible in the main tables.

Table 13: **Architecture-transfer sanity check on U-ViT.** CFS probes early, middle, and late U-ViT block outputs instead of U-Net encoder/decoder hooks. All variants use one canonical low-noise level, one backbone forward, token mean/std pooling, and an ID-only diagonal score. The output baseline uses the same checkpoint, level, and one-forward budget, but scores only the final reconstruction error. Averages are computed over 12 ordered pairs: for each ID dataset in {CIFAR-10, SVHN, CelebA32}, we evaluate against the other two source datasets plus CIFAR-100 and DTD as OOD.

Backbone	Method	Region / signal	AvgAUROC \uparrow	AvgFPR95 \downarrow	Cost \downarrow
U-ViT-CIFAR10	Output recon. MSE	output	0.778	0.653	1F
U-ViT-CIFAR10	CFS-early	in_blocks.2	0.872	0.356	1F
U-ViT-CIFAR10	CFS-mid	mid_block	0.874	0.292	1F
U-ViT-CIFAR10	CFS-late	out_blocks.2	<u>0.891</u>	0.213	1F
U-ViT-CIFAR10	CFS-early+late	in_blocks.2+out_blocks.2	0.896	<u>0.238</u>	1F

Table 14: **Per-source breakdown of the U-ViT architecture-transfer sanity check.** Each cell reports the average over the four OOD datasets associated with the corresponding ID source. The output baseline uses final reconstruction MSE, while CFS variants use internal token snapshots. The main failure mode is CIFAR-10 as ID, especially against CelebA32 and CIFAR-100.

Method	Metric	ID=SVHN	ID=CIFAR-10	ID=CelebA32
Output recon. MSE	AvgAUROC \uparrow	0.927	0.594	0.813
Output recon. MSE	AvgFPR95 \downarrow	0.467	0.803	0.687

CFS-early+late	AvgAUROC \uparrow	<u>0.985</u>	0.719	0.984
CFS-early+late	AvgFPR95 \downarrow	<u>0.072</u>	0.575	<u>0.066</u>

G Full Source-Family Robustness Results

This section tests whether the main representation-space pattern is tied to one checkpoint family or survives a controlled change in the frozen source representation.

We report the full pairwise breakdown for the alternative CelebA32-source checkpoint family. Tables 17 and 18 provide the detailed AUROC and FPR95 results. The goal is to test whether the source-family change modifies only absolute performance or also the qualitative ranking between representation-space and output-space methods.

A source-family change modifies the representation bias of the frozen checkpoint. The relevant question is therefore not whether absolute numbers remain identical, but whether the ranking and the representation-versus-output-space contrast remain qualitatively stable.

The full tables support the same broad conclusion as the compact main-paper summary: changing the source family shifts absolute numbers but does not erase the main pattern. Sparse representation-space probing remains highly competitive, and the contrast between CFS and broader output-space baselines survives the change in frozen source representation.

H External Positioning Against Prior Reported Diffusion Results

This section provides external context by comparing CFS to previously reported diffusion-based CIFAR-scale results.

Table 19 shows that the sparse representation-space advantage of CFS is not confined to the controlled MBE setting. Even outside backbone-equated evaluation, CFS remains competitive with or stronger than previously reported single-checkpoint diffusion results, while using only one backbone evaluation per image.

Table 15: **Full per-pair AUROC on the CIFAR-scale benchmark under the primary CIFAR10-source policy.** Each entry corresponds to one ID→OOD pair. The same fixed shared-source protocol is used for all methods. All metrics are reported with three decimal places.

H.1 Positioning against DLSR on its native published settings

DLSR is the closest prior in spirit, but it studies a different object: learned feature reconstruction rather than sparse probing of native frozen states. It also falls outside our MBE protocol. Since DLSR is only available on the ID/OOD pairs supported by its published setup, we report in Table 20 a positioning comparison on the DLSR-native overlapping subset, without treating this table as part of the main MBE claim.

DLSR is therefore evaluated only on pairs supported by the original protocol/repo. The full cross-ID benchmark would require extending the original DLSR training and evaluation pipeline beyond the published setup.

I Checkpoint-Controlled Large-Scale Results

This appendix reports a checkpoint-controlled large-scale comparison on ImageNet200 and ImageNet1K using a single official ImageNet-64 improved-diffusion checkpoint. These experiments are not meant to replace the controlled CIFAR-scale evidence in the main paper. Their role is narrower: to test whether the same representation-first signal remains informative in a substantially harder large-scale regime under a fixed backbone.

In all experiments below, all methods use the same official ImageNet-64 improved-diffusion checkpoint (imagenet64_uncond_100M_1500K.pt). We evaluate on two near-OOD regimes, **NINCO** and **SSB-hard**, and one far-OOD regime, **Textures**. Unless stated otherwise, both CFS variants use a single low-noise canonical level and therefore retain a logical test-time cost of $1F + 0J$, whereas MSMA and DIFFPATH use $10F + 0J$.

Table 21 reports the resulting large-scale comparison. In addition to the primary main-paper operating point CFS(1×2), we also include the ultra-sparse decoder-only companion CFS_{dec}(1×1).

These numbers constitute a checkpoint-controlled stress test of whether the representation-first signal remains informative outside the controlled CIFAR-scale regime

Table 17: **Full per-pair AUROC on the CIFAR-scale benchmark under the alternative CelebA32-source policy.** This is the detailed source-family robustness breakdown complementary to the main-paper summary. All metrics are reported with three decimal places.

This checkpoint-controlled large-scale view yields a clear pattern. First, near-OOD ImageNet-scale detection remains difficult for all methods, especially on SSB-hard. Second, Textures is substantially more discriminative and reveals a clear advantage for sparse CFS probes over MSMA and DIFFPATH. Third, under this official improved-backbone setting, the sparse decoder-only variant CFS_{dec}(1×1) is consistently slightly stronger than CFS(1×2) on both ImageNet200 and ImageNet1K, while preserving the same 1^F logical cost.

Interestingly, in the ImageNet-scale checkpoint-controlled setting, CFS_{dec}(1×1) is slightly stronger than CFS(1×2). The result suggests that, in this harder large-scale regime, the conditional encoder residual of Theorem 1, is either small or not reliably exploitable by the lightweight diagonal score, so the late decoder snapshot remains the most robust sparse probe.

The NINCO and SSB-hard results indicate that large-scale semantic OOD remains difficult for all diffusion-based methods under this fixed single-backbone evaluation setting.

J Implementation and Configuration Details

This section reports the implementation details needed to reproduce the main CFS runs and the corresponding ablations. All methods are evaluated through the shared MBE adapter described in Appendix C. Unless stated otherwise, images are normalized to $[-1, 1]$, the test-time Monte Carlo count is one, and all reported main-paper methods use OOD-high scores.

J.1 CFS probing configuration

Table 22 reports the sparse probing configuration used for the primary one-level CFS runs. The same canonical probing setup is used for CFS(1×2), while decoder-only variants restrict the retained region to the decoder side.

Table 19: **External positioning against prior reported diffusion-based results on the CIFAR-scale benchmark.** Rows above the final block are taken from prior work. We separate: (i) prior diffusion-based methods reported in ID-specific settings, and (ii) single-checkpoint diffusion methods using one frozen checkpoint across multiple ID/OOD pairs.

Table 20: **Positioning against DLSR on its native published evaluation pairs.** DLSR lies outside the MBE protocol and uses an additional learned feature-reconstruction module, so we do not report a backbone-forward-equivalent logical cost for it. For our methods, Cost denotes the backbone-forward logical cost. Averages are computed over the non-missing overlapping entries of each method.

For the main results, each selected slot is scored with the lightweight diagonal statistic in Eq. (7). Table 23 reports the corresponding ID-only head configuration. For the head-sensitivity ablation in Appendix E.6, we additionally evaluate stronger ID-only heads on the same sparse representation.

Pooling. The main-paper pooling rule is the one defined in Eq. (6): channel-wise spatial mean concatenated with channel-wise spatial standard deviation. Mean-only and std-only variants are treated as pooling ablations in Appendix E.5, not as the default CFS configuration.

J.2 Compute profiling protocol

We profile wall-clock inference cost using the same benchmark runner as the reported experiments in Table 24. For each method, profiling is performed after ID-only fitting and measures the full scoring path: canonical corruption, backbone evaluations, hook or output extraction, and score computation. We use 5 warm-up batches and 50 measured batches, with CUDA synchronization before and after the measured region. Peak memory is measured with `torch.cuda.max_memory_allocated`. All timings are reported at the same batch size used in the benchmark.

We distinguish logical cost from measured runtime. Logical cost counts backbone evaluations per image, $\#F$; measured runtime additionally includes feature pooling, density-head evaluation, data movement, and method-specific aggregation overhead.

All profiles in Table 24 were obtained on a single NVIDIA GeForce RTX 4060 Laptop GPU with batch size 128, and PyTorch 2.10.0. For DDPM-OOD with EDM, we report the logical cost but omit wall-clock profiling because the 364F scoring path is prohibitively expensive; the improved-diffusion profile already illustrates this order-of-magnitude cost.

Table 21: **Checkpoint-controlled large-scale comparison on the official ImageNet-64 improved-diffusion backbone.** All methods use the same official improved-diffusion checkpoint (imagenet64_uncond_100M_1500K.pt). We report AUROC on NINCO, SSB-hard, and Textures, together with averaged AUROC, AUPR, and FPR95 over these three OOD sets. The logical test-time cost of the displayed CFS variants is $1F$; for MSMA and DIFFPATH it is $10F$.

ID	Method	NINCO \uparrow	SSB-hard \uparrow	Textures \uparrow	Avg. AUROC \uparrow	Avg. AUPR \uparrow	Avg. FPR95 \downarrow	Cost

Table 22: **Sparse CFS probing configuration.** This configuration specifies the canonical level, hook policy, pooling rule, Monte Carlo settings, and ID-only hook-selection proxy used for the main sparse probing runs.

Parameter	Value
Number of selected canonical levels K_c	1
Candidate canonical grid K_{grid}	1
Explicit canonical levels	[5.0]
Pooling rule	channel-wise mean + standard deviation
Dynamics features	disabled
Hook policy	sparse_ed_id
Region mode for CFS(1×2)	encoder + decoder
Retained encoder hooks	1
Retained decoder hooks	1
Fit-time Monte Carlo count MC_{fit}	1
Test-time Monte Carlo count MC_{test}	1
Maximum fit batches	64
Internal batch size	64
ID probe batches for hook proxy	1
Maximum candidates per region	4
Clamping	disabled
Numerical floor ε	10^{-6}

K Broader Impact and Responsible Use

This work studies post-hoc OOD detection for frozen diffusion backbones. A potential positive impact is improved reliability and auditability of vision systems: sparse internal probes may help identify inputs that fall outside an evaluation reference distribution, while keeping test-time cost low and making protocol confounders explicit.

The main negative risk is over-reliance. An OOD score is not a certificate of safety, correctness, or fairness, and false negatives may create unwarranted confidence in high-stakes settings. This is especially important for sensitive visual domains such as medical imaging, biometric analysis, surveillance, or safety-critical autonomy, where dataset shift, demographic imbalance, or acquisition bias may produce failures not captured by the evaluation protocol.

Our method is intended as a diagnostic and benchmarking tool rather than a standalone deployment safeguard. In practical use, it should be combined with domain-specific validation, calibrated thresholds, uncertainty auditing, and human oversight where decisions may affect people.

Table 23: **Default ID-only head configuration for the main CFS results.** The main paper uses the diagonal score to keep the detector lightweight and to avoid conflating representation quality with downstream head capacity.

Parameter	Value
Head type	diagonal Gaussian / diagonal Mahalanobis score
Slot statistics	ID-only mean and diagonal variance
Variance floor	10^{-6}
Feature pooling	channel-wise mean + standard deviation
Slot aggregation	uniform average over selected slots
KNN head	not used in main results
GMM head	not used in main results
Shrinkage covariance head	not used in main results

Table 24: **Representative compute profile on the CIFAR-scale benchmark.** Timings are measured after ID-only fitting using the full scoring path with 5 warm-up batches and 50 measured batches. GPU-hours estimate the fit plus evaluation cost for one ID-vs-OOD benchmark run under the reported split sizes.

Method	Backbone	Logical cost	Fit time (s)	ms/img	Peak mem. (GB)	GPU-hours
MSMA	improved	10F	160.8	19.52	0.66	0.41
